It will have been observed in Table XIII, that where a weakly buffered Ringer's solution was used, the production of acetoacetic acid from valeric and heptanoic acids compared with those from the even-numbered acids seems high relative to the figures previously obtained in a glycerophosphate medium. It occurred to us that this phenomenon might be due to a relatively low  $p_H$  in these experiments, caused by the greater acidifying effect of respiratory carbon dioxide when the initial carbon dioxide content of the gas mixture is low (1.5%). We have therefore compared (Table XIV) the relative activities of the odd- and even-numbered acids in more strongly buffered media and have obtained some indication that at a lower  $p_H$  the acetoacetic acid production of the odd-numbered acid is raised relatively to that of a neighbouring even-numbered acid.

Table XIV. *Effect of  $p_H$  on relative acetoacetic acid production from odd- and even-numbered acids.*

*The effect of benzoate on the oxidation of fatty acids.*

We have already shown in Part I that benzoate at low concentrations inhibits the oxidation of butyric and crotonic acids to acetoacetic acid by guinea-pig liver. The same substance has been examined here with regard to its inhibiting action on the formation of acetoacetic acid from fatty acids by rat liver.

As will be seen from Table XV, 0.002 *M* benzoate lowers  $Q_{Ac}$  by some 50% (a) when there is no substrate added, (b) when acetic acid is present and (c) when the substrate is butyrate. It should be noted that the respiration in the absence of added substrates is unaffected by benzoate at concentrations up to 0.04 *M*. Benzoate at low concentrations is evidently quite a specific poison for tissue processes.

Benzoate, however, in contrast to its effect on  $Q_{Ac}$  in presence of acetate and butyrate, has a much smaller effect on the production of acetoacetic acid from hexanoic, octanoic and decanoic acids (Table XV).

As a result, when the acetoacetic acid productions in the presence of benzoate from the various fatty acids are compared in any one experiment it is found that  $Q_{Ac}$  from butyrate is lower than that from hexanoic, octanoic and decanoic acids.

Table XV. *Effect of benzoate on formation of acetoacetic acid.*

Rat liver. Oxygen. Glycerophosphate buffer.

5	0	4.70	4.90	4.68	3.07
6	0.005	2.62	4.22	4.57	3.12
7	0.0075	1.77	3.09	3.97	3.10
8	0.01	2.59	3.92	4.09	4.01

*Same as above in relative units. Values of  $Q_{Ac}$  in presence of benzoate.*

Exp.	Concentration benzoate	Butyrate	Hexanoate	Octanoate	Decanoate
5	0	153	160	152	(100)
6	0.005	84	135	146	(100)
7	0.0075	57	100	128	(100)
8	0.01	65	98	102	(100)

When the concentration of benzoate is increased, it is possible to find conditions where, similarly,  $Q_{Ac}$  from hexanoate is lower than that from octanoic acid. Probably conditions of benzoate concentration could be found under which decanoic acid would form acetoacetic acid faster than do octanoic and hexanoic acids.

In the absence of benzoate the values of  $Q_{Ac}$  are approximately equal with butyrate, hexanoate and octanoate, but rather lower with decanoate. The behaviour in absence of benzoate may thus be compatible with the  $\beta$ -oxidation mechanism according to which decanoic acid is transformed successively into octanoic, hexanoic and butyric acids before acetoacetic acid is formed. The behaviour in presence of benzoate, however, is very difficult to explain on this theory of fatty acid breakdown.

Before considering the subject further, we should note that it has also been found that the same alteration in relative rates with the different fatty acids by benzoate is shown when we measure the total ketone production instead of acetoacetic acid production. Reference to Table XVI shows in the case of rat liver that the findings are the same, and that the total ketone production from butyric acid can be lowered below the level shown by the other fatty acids.

These results clearly compel us to abandon the mechanism proposed by Embden. The formation of ketone bodies from the higher fatty acids appears not to be necessarily preceded by their degradation to lower fatty acids and

Table XVI. *Total ketone production in presence of benzoate.*Ringer's solution (95 %  $O_2$  + 5 %  $CO_2$ ; 0.025  $M$   $NaHCO_3$ ).

	$Q_{ket}$ in presence of			
	Butyrate 0.02 $M$	Hexanoate 0.007 $M$	Octanoate 0.006 $M$	Decanoate 0.0025 $M$
Rat liver, 0.01 $M$ benzoate	1.54	2.48	3.13	1.95
Rat liver, 0.015 $M$ benzoate	2.28	3.08	2.63	—
Guinea-pig liver, 0.01 $M$ benzoate	1.39	0.87	—	—
Guinea-pig liver, 0.01 $M$ benzoate	0.85	0.54	0.61	0.71

finally to butyric acid before ketone bodies are formed. No escape from this conclusion seems possible. In our experiments butyric acid is the acid with which optimum conditions are most easily obtained, since excessive concentrations do not affect the oxidation to ketone bodies. It is much more certain that conditions are optimum for butyrate than for the higher fatty acids, and yet in presence of benzoate it forms ketone bodies at a lower rate than do the higher fatty acids.

It remains to consider our experiments further in the light of one or two possibilities.

(1) It is possible that a part of the ketone bodies from the higher fatty acids arises through acetic acid which may be split off from them as an intermediary. Our experiments with acetic acid show however that acetoacetic acid production from it is as much inhibited by benzoate as is that from butyrate, and is in any case small. The view that acetic acid is an intermediary is therefore of little importance in this connection.

(2) In the case of octanoic and higher acids, it is conceivable that a molecule of fatty acid might give rise to two or more molecules of acetoacetic acid, and that one of these molecules might be formed through butyric acid as an intermediary. On this view the inhibition of ketone body formation in the case of octanoic acid should be at least half as great as with butyric acid.

In the case of guinea-pig liver the inhibitory effect of benzoate does not vary so much from one fatty acid to another (Tables XVI and XVII), and we cannot conclude from our experiments on this tissue with benzoate that the Embden mechanism is invalid. Apparently fluoride, like benzoate, inhibits acetoacetic acid production from the higher fatty acids rather less than from butyric acid.

Table XVII. *Effect of inhibitors on guinea-pig liver.*Exp. 1. (Ringer's solution: 5 %  $CO_2$ ; 0.025  $M$   $NaHCO_3$ .)

Conc. butyrate ( $M$ )	0.01	0.01	—	—
Conc. octanoate ( $M$ )	—	—	0.01	0.01
Conc. benzoate ( $M$ )	—	0.002	—	0.002
$Q_{O_2}$	1.78	0.74	1.79	0.90
% decrease in $Q_{Ac}$	—	58	—	50

Exp. 2. (Glycerophosphate buffer.)

Conc. butyrate ( $M$ )	—	0.01	0.01	—	—
Conc. octanoate ( $M$ )	—	—	—	0.006	0.006
Conc. fluoride ( $M$ )	—	—	0.0031	—	0.0031
$Q_{O_2}$	4.66	8.18	5.67	9.25	6.12
$Q_{Ac}$	0.18	2.27	0.67	1.93	0.84
% decrease in $Q_{Ac}$	—	—	70	—	57

Exp. 3. (Glycerophosphate buffer.)

Conc. butyrate ( $M$ )	—	—	0.01	0.01
Conc. arsenite ( $M$ )	—	0.001	—	0.001
$Q_{O_2}$	4.53	1.96	8.68	2.23
$Q_{Ac}$	0.20	0.02	2.95	0.40

An experiment in Table XVII shows in an interesting way how much more specific fluoride and benzoate are in their actions on acetoacetic acid production than is arsenite. Arsenite inhibits acetoacetic acid production strongly, but the respiration also is greatly inhibited, showing that other tissue-processes are greatly affected.

#### THE MECHANISMS OF THE OXIDATIONS.

The  $\beta$ -oxidation theory of Knoop proposes that fatty acids are oxidised in a series of stages, in each of which the  $\beta$ -carbon atom of a fatty acid is attacked in such a manner that loss of two carbon atoms follows. The experiments of Embden led him to suggest that for the even-numbered fatty acids the stages led through the following substances:

Embden found that the odd-numbered acids formed no acetoacetic acid, which is the result anticipated if these acids also undergo  $\beta$ -oxidation.

We have found, in accordance with Embden, that the rate of production of acetoacetic acid from fatty acids varies in an alternate manner, the even-numbered acids producing much more acetoacetic acid than their odd-numbered neighbours. A new result is that, with guinea-pig liver at least, the odd-numbered fatty acids—apart from formic and propionic acids—also give rise to small but significant amounts of acetoacetic acid.

It is therefore likely that  $\beta$ -oxidation, if it occurs at all, is not the only type of oxidation which takes place with the odd-numbered acids.

The fatty acids produce  $\beta$ -hydroxybutyric acid as well as acetoacetic acid. The hydroxy-acid is probably produced by reduction of acetoacetic acid, for this has been shown to be true in the case of crotonic and butyric acids [Jowett and Quastel, 1935, 1]. The production of total ketones is therefore in all probability the best measure of the gross acetoacetic acid production.

The increase in respiration of guinea-pig liver brought about by odd-numbered acids is greater than that due to their even-numbered neighbours, which suggests that the odd-numbered acids are more completely oxidised. This more complete oxidation would be expected if odd-numbered acids yield a three-carbon acid which is readily oxidised by the liver, in contrast to acetoacetic acid, which is little oxidised.

The yields of total ketone bodies obtained from the even-numbered acids of 4 to 10 carbon atoms with guinea-pig liver are of the order of one molecule of ketone bodies per molecule of fatty acid.

So far, then, we have a number of facts which are in general accord with the  $\beta$ -oxidation theory, although there is a suggestion that the odd-numbered acids possess also another mode of oxidation which may not be quantitatively of great importance. The facts next to be considered may also be interpreted on the  $\beta$ -oxidation theory, if we add to this an assumption regarding the nature of the product formed from the two carbon atoms lost in each stage of oxidation. We have, in fact, found that fixed acid is produced during the oxidation of the higher fatty acids by guinea-pig liver. The acid (or acids) has not yet been identified. If it should be acetic acid, or another 2-carbon acid, our results regarding acid production are in qualitative agreement with the predictions of the  $\beta$ -oxidation theory. These results have already been discussed.

The suggestion that acetic acid is a product of fatty acid oxidation leads to the query whether acetic acid might not be the source of the acetoacetic acid formed by the higher odd-numbered fatty acids. Since these acids form acetoacetic acid at a higher rate than does acetic acid with guinea-pig liver, it is

## (2) Odd-numbered acid:

(a)  $\beta$ -oxidation(b)  $\alpha\gamma$ -oxidation

The detailed working out of our hypothesis is still, as just pointed out, a matter of speculation. We cannot dismiss the possibility that even-numbered fatty acids may undergo oxidation at their  $\alpha$ -,  $\gamma$ -,  $\epsilon$ -... carbon atoms, or the possibility that  $\omega$ -oxidation may occur with the higher fatty acids to some considerable extent.

We can do little more now than present the hypothesis that oxidation proceeds along the whole chain of a fatty acid molecule at alternate carbon atoms, with the ultimate formation of acetoacetic acid and other acid products. Oxidation at the  $\beta$ -,  $\delta$ -... carbon atoms is considered to be the major process in the oxidation of fatty acids containing four or more carbon atoms.

## SUMMARY.

1. An investigation has been made of the formation of acetoacetic and  $\beta$ -hydroxybutyric acids, resulting from the oxidation of the normal saturated fatty acids containing from two to ten carbon atoms, in the presence of rat and guinea-pig liver. Van Slyke's method for estimating ketone bodies is used on a micro-scale.

2. Acetoacetic acid is probably the only  $\beta$ -keto-acid produced in significant quantities by the oxidation of fatty acids.

3. Acids of four, six and eight carbon atoms produce acetoacetic acid most rapidly. The ten-carbon acid is slightly less active and acetic acid considerably less active.

4. Acids of five, seven and nine carbon atoms produce acetoacetic acid at small but significant rates with guinea-pig liver. Propionic acid does not form acetoacetic acid.

5. The greater increase in the respiration of liver brought about by the odd-numbered fatty acids suggests that these are more completely burned to carbon-dioxide and water than their even-numbered neighbours.

6. In the case of guinea-pig liver, about one molecule of ketone bodies is produced per molecule of hexanoic or octanoic acid, and rather less is produced with decanoic acid. The yield of ketone bodies from butyric acid is considerably lower.

7. With all fatty acids higher than valeric acid, oxidation results in the formation of fixed acid, which is greater with the even-numbered fatty acids than with the odd-numbered fatty acids. The nature of the fixed acid produced,

which is neither acetoacetic nor  $\beta$ -hydroxybutyric acid, has not been determined. The oxidation of propionic and valeric acids results in disappearance of fixed acid.

8. Sodium benzoate inhibits the acetoacetic acid and total ketone body production from butyric acid to a greater extent than from the higher fatty acids in the presence of rat liver. The inhibition decreases on ascending the series of even-numbered acids.

9. The results are discussed in relation to the theory of successive  $\beta$ -oxidation, which is shown to be inadequate to explain the facts. A hypothesis of "multiple alternate oxidation" is put forward, according to which the fatty acids are supposed to be oxidised at alternate carbon atoms along the whole length of the chain before breakdown to acetoacetic and other acids takes place.

# CCLVII. STUDIES IN FAT METABOLISM.

## III. THE FORMATION AND BREAKDOWN OF ACETOACETIC ACID IN ANIMAL TISSUES.

BY MAURICE JOWETT<sup>1</sup> AND JUDA HIRSCH QUASTEL.

*From the Biochemical Laboratory, Cardiff City Mental Hospital.*

*(Received July 11th, 1935.)*

THIS paper is concerned with measurements of the rates of acetoacetic acid formation from fatty acids in tissues other than liver. The oxidation of fatty acids in the liver has been dealt with in Parts I and II of this series [Jowett and Quastel, 1935, 1, 2]. The paper also describes the effect of sodium malonate in increasing acetoacetic acid formation in the liver—an effect which is largely due to its inhibitory action on acetoacetic acid breakdown—and the effects of atoxyl and quinine in depressing the “spontaneous” acetoacetic acid formation in this organ. Measurements have been made of the rate of destruction of acetoacetic acid by tissues.

### *Acetoacetic acid production in tissues other than liver.*

There is much evidence that the liver is the most important organ for fat metabolism in the body. It has been suggested that other organs may also oxidise fat, but the evidence in favour of this view is apparently not very strong.

Formation of ketone bodies by other organs does not appear to have been shown by perfusion methods. Embden and Kalberlah [1906] found no formation of acetone or acetoacetic acid by dog muscle, lung or kidney. Snapper *et al.* [1926] found no ketone body formation on perfusing kidneys with butyric acid, and neither kidney nor lung oxidised  $\beta$ -hydroxybutyric acid to acetoacetic acid.

On the other hand Himwich *et al.* [1931] found that in intact phlorhizinised and depancreatized dogs the muscles and the organs drained by the portal vein sometimes liberated acetone bodies into the blood and sometimes removed them from the blood.

A number of experiments<sup>2</sup> has been carried out on the respiration and acetoacetic acid production by tissues other than liver. The experiments have been sufficient to show some new facts.

In the absence of added fatty acids, kidney and rat brain and spleen show no measurable production of acetoacetic acid (Table I), for values of  $Q_A$  less than 0.2 are within the experimental error. On the other hand rat testis gives a low but measurable production of acetoacetic acid.

In the presence of added fatty acids—butyric and hexanoic acids—all the tissues examined, except brain, produce small but definite quantities of acetoacetic acid, and the production of acetoacetic acid is usually accompanied by a definite increase in respiration. We have therefore grounds for believing that kidney, spleen and testis have a definite fat metabolism. No evidence of acetoacetic acid production under anaerobic conditions has been found.

<sup>1</sup> Beit Memorial Research Fellow.

<sup>2</sup> Details of the experimental methods used in this paper are given by Jowett and Quastel [1935, 1, 2].

		$Q_{Ac}$	—	0.0*	—	2.16†	—

\* In presence and absence of glucose.

† In absence of glucose. In presence of glucose the values  $Q_{O_2} = 12.2$ ,  $Q_{Ac} = 1.38$  were found.

All the tissues examined produce acetoacetic acid from *dl*- $\beta$ -hydroxybutyric acid. This is further evidence, in addition to that given in Part I, that the mechanism of oxidation of  $\beta$ -hydroxybutyric acid is quite different from that of saturated fatty acids, for brain will oxidise  $\beta$ -hydroxybutyric acid but not butyric acid.

*The effect of potassium and calcium ions on  $Q_{Ac}$  from  $\beta$ -hydroxybutyric acid.*

In an experiment (see Table II) on the effect of varying the potassium and calcium ion concentrations on the rate of formation of acetoacetic acid from  $\beta$ -hydroxybutyric acid by guinea-pig kidney, we found a similar result to one

Table II. *dl*- $\beta$ -Hydroxybutyrate 0.01 M.

Guinea-pig kidney	K <sup>+</sup>	0	0.0005	0.002
	Ca <sup>++</sup>	0	0.00025	0.001
	$Q_{O_2}$	16.0	19.1	21.9
	$Q_{Ac}$	4.07	3.16	3.18

formerly found with guinea-pig liver (Part I), namely that the rate is highest in absence of potassium and calcium. As will be shown later, potassium and calcium ions stimulate the removal of acetoacetic acid by guinea-pig kidney, and we consider therefore that the gross rate of production of acetoacetic acid in the present experiment is probably unaffected by the ionic environment, although the nett (observed) rate is affected.

It may be remarked here that kidney, testis and spleen all have the power of destroying acetoacetic acid, and the observed rates of production of acetoacetic acid from fatty acids are of course lowered for this reason below the rates that they would show if the destruction of acetoacetic acid were prevented.

*Fat metabolism of tissues and respiratory quotients.*

It is interesting to correlate the probable possession of fat metabolism by kidney, spleen and testis with the fact that all these tissues have respiratory quotients below unity [Dickens and Šimer, 1930; 1931]. The possession of an R.Q. below 1, or even below 0.8, cannot of itself inform us in the case of isolated tissues of the nature of the metabolism. The end-products of metabolism are largely known with the intact organism, and the R.Q. of the organism can therefore be interpreted to some extent. With individual organs, it is improbable that each organ is a self-contained unit which metabolises only carbohydrate, protein and fat, and produces the same end-products as does the whole organism. It is more likely that an extensive chemical symbiosis is to be found among the various tissues of an organism, and that metabolic processes begun in one tissue are frequently completed in another.

However, now that it has been shown that kidney, spleen and testis can oxidise fatty acids, the fact that these tissues have an R.Q. below unity in presence of glucose is probably an indication that these tissues do metabolise fatty substances. We may note on the other hand that brain, which, according to our findings (Table I) and those of Quastel and Wheatley [1933], probably does not oxidise fatty acids, has an R.Q. of unity.

*The respiratory quotient of fat oxidation in the liver.*

If tristearin is oxidised completely to carbon dioxide and water, the process has a respiratory quotient of 0.70. The higher fats generally give not dissimilar quotients for complete oxidation, and for this reason it is customary to assign to the oxidation of fat in the body an R.Q. of 0.7.

Fat is not completely oxidised in the liver, the process being completed elsewhere in the body. For we have found with rat liver slices a rate of production of acetoacetic acid, in the absence of added fatty acids, which indicates that the oxidation of fat is far from complete. Probably other products of incomplete oxidation are formed—acetone,  $\beta$ -hydroxybutyric acid and others—but we have no data concerning them.

We have therefore insufficient information to enable us to calculate the R.Q. of fat oxidation in the liver, but it appears that even calculations based on the available information are sufficient to show that the R.Q. of the process is probably much lower than 0.7.

Let us assume that tristearin is the fat burned, and attempt to account for the values  $Q_{O_2} = 1.0$  and  $Q_{Ac} = 1.1$  which we have found for rat liver.

(1) Let us first assume that the respiration is entirely due to oxidation of fat. Then we can account approximately for the acetoacetic acid production by the equation:

For then if  $Q_{O_2} = 1.0$ ,  $Q_{Ac} = 1.04$  and the R.Q. of the process is 0.57. If other products of incomplete combustion are formed as well, the R.Q. will be lower than 0.57.

(2) It is unlikely that fat is the only substrate burned in the liver of a normally fed animal. We will therefore make an alternative calculation on the basis that half the oxygen respired oxidises fat, and that the other half oxidises carbohydrate completely. This leads approximately to the equation:

Then for the fat oxidation  $Q_{O_2}=5$ ,  $Q_{Ac}=0.99$  and the R.Q. is 0.46. For the whole respiration of the liver we have then the values  $Q_{O_2}=10$ , and R.Q.=0.73.

Many such calculations of varying degrees of probability could be made. The two calculations given show however that, if the acetoacetic acid produced by rat liver arises from a fat of the type common in foodstuffs, then the R.Q. of the fat oxidation is almost certainly below 0.6, and may be much lower. How much lower it is depends on how far oxidation of other substances takes place, and on the quantity and nature of other products of incomplete combustion of fat.

Another probable result of these calculations is that, on the same assumptions, a higher fatty acid gives rise to more than one molecule of acetoacetic acid.

It may be noted, as an experimental point in connection with determination of the R.Q. and acid production with slices of rat liver, that the breakdown of acetoacetic acid in acid solutions has not been allowed for in former work, and that the existing values in the literature are therefore somewhat in error. Gemmill and Holmes [1935] have noted this point, but have not corrected for it.

#### *The destruction of acetoacetic acid by tissues.*

Some experiments have been carried out in which the rate of destruction of acetoacetic acid by tissue slices has been measured. In these experiments, which are to be regarded therefore as of a preliminary nature, the fate of the acetoacetic acid has not been determined. It has been found by perfusion methods [Snapper and Grünbaum, 1927, 1] that the liver reduces acetoacetic acid to  $\beta$ -hydroxybutyric acid, while the kidney [Snapper and Grünbaum, 1927, 2] effects the same reduction but mainly brings about a disappearance of ketone bodies. The nature of the action of other tissues has not been determined.

The acetoacetic acid has been determined in these experiments as usual by the manometric method (see Part I) after removing the tissue-slices at the end of the period of two hours in the bath at 37°. A "control" vessel containing sodium acetoacetate without tissue has always been similarly kept in the bath to obtain an initial value for the acetoacetic acid content. A correction for the amount of acetoacetic acid removed with the tissue slices has been applied on the basis that equal distribution occurs between tissue and medium. The correction may be faulty and may lead to an appreciable error when the rate of destruction is low.

The experiments show that guinea-pig kidney destroys acetoacetic acid at a considerable rate under the usual aerobic conditions.

A new finding is that the kidney retains some power to destroy acetoacetic acid when the conditions are anaerobic. The anaerobic rate of disappearance is some 30–40% of the aerobic rate. Under anaerobic conditions the presence of acetoacetate enhances the small acid production that is shown by guinea-pig kidney in absence of added glucose. Whether the effect is due to a stimulation of glycolysis or whether the destruction of acetoacetic acid results in appearance of a new acid group must be left for further investigation to decide.

Lactate and glucose increase to some extent the rate of disappearance of acetoacetic acid, both aerobically and anaerobically, but their effects are not very marked.

When the potassium and calcium ions normally present in the media are absent, the rate of destruction of acetoacetic acid is lessened. It will be remembered that it has already been suggested that this effect accounts for an apparent stimulation of acetoacetic acid production from  $\beta$ -hydroxybutyric acid by absence of potassium and calcium ions. These results are all noted in Table III.

It has been found (see Table IV) that other tissues also bring about disappearance of acetoacetic acid. Of those examined rat kidney is the most active. Spleen is less so, and testis and liver are relatively inactive.

The power of tissues to remove acetoacetic acid lessens the nett formation of acetoacetic acid which results from oxidation of added fatty acids. In the case of kidney the effect will be great, but in the case of liver it is less. According to the work of Snapper and Grünbaum [1927, 1] liver does not destroy ketone bodies to any definite extent, and its main action on acetoacetic acid will be to

Table IV.

convert it into  $\beta$ -hydroxybutyric acid; the rate of this process is quite appreciable, particularly when fatty acids are present as sources of acetoacetic acid (see Part II).

When both acetoacetic acid and  $\beta$ -hydroxybutyric acid are present in the medium, they will be interconverted. The experiment given in Table IV, together with others already quoted in Part II, suggests that the rates of interconversion are of the same order of magnitude.

*The effects of malonate on respiration and acetoacetic acid production.*

None of the substances hitherto examined has shown any very definite accelerating effect on the production of acetoacetic acid by the liver.

Malonate, however (which has been used in all these experiments at a concentration of 0.04–0.05 *M*) increases the rate of acetoacetic acid production by

rat and guinea-pig liver in the absence of added substrates. With guinea-pig liver  $Q_{Ac}$  rises from about 0.2 to 0.68 (mean of 8 experiments, average deviation  $\pm 0.12$ , range 0.38–0.82), and with rat liver  $Q_{Ac}$  rises from 1.1 to 2.38 (3 experiments, range 2.01–2.65). These experiments were made, as usual, under aerobic conditions and in presence of glycerophosphate.

The respiration of rat liver in presence of malonate undergoes a progressive lowering. Guinea-pig liver is oppositely affected, the respiration being maintained at its original level by malonate (Fig. 1). The reasons for these effects are still speculative.

It seemed possible that malonate might be increasing  $Q_{Ac}$  by undergoing decarboxylation to acetate, followed by formation of acetoacetate from acetate. No evidence that decarboxylation of malonate takes place was found on measuring the acid-base change undergone by rat liver in presence of malonate in Ringer's solution.

In absence of malonate the value +1.9 was found for  $Q_S$ , and in its presence the value +2.1. We therefore reject the idea that the extra acetoacetic acid produced in presence of malonate arises by chemical transformation of the malonate ion.

We prefer instead to suggest that malonate has an inhibitory action on the decomposition of acetoacetic acid by liver and in this way enhances the observed  $Q_{Ac}$  values.

Experiments which show that this suggestion is correct have been made and will be reported upon in a later communication. A considerable inhibition of acetoacetic acid breakdown by malonate in presence of rat liver has been found.

Evidence has been obtained that malonate has some inhibitory action on the oxidation of fatty acids. The evidence rests mainly on the effect of malonate on the increase in respiration which fatty acids bring about.

Reference to Table V shows that in the case of acetate this increase is practically abolished by malonate, and with propionate and butyrate the increase is diminished. In the case of propionate the evidence from the respiration receives confirmation from an experiment on the acid production by propionate in presence of guinea-pig liver: malonate lowers  $Q_S$  from  $-2.35$  to  $-1.15$ .

The data obtained concurrently on the acetoacetic acid production in presence of malonate are less easy to interpret quantitatively, the evidence of a decrease in  $Q_{Ac}$  being less definite, since it is uncertain whether additivity or competition is to be assumed between the  $Q_{Ac}$  in absence of fatty acid and the acetoacetic acid due to its presence.

Since malonate inhibits acetoacetic acid breakdown by liver there is no difficulty in understanding that a partial inhibition of fatty acid oxidation need not lead to a diminution of nett acetoacetic acid production.

These results provide evidence that malonate, which was known previously only to inhibit the oxidation of succinic acid [Quastel and Whetham, 1925; Quastel and Wheatley, 1931] has also an inhibitory action on the oxidation of

Fig. 1. The effect of malonate on respiration.

certain fatty acids and on the breakdown of acetoacetic acid. It is noteworthy that these substances all possess a terminal  $-\text{CH}_2\text{COOH}$  group.

From the low yield of ketone bodies obtained with guinea-pig liver from butyric acid, it is probable that part of the butyric acid undergoes oxidation to products other than acetoacetic acid, and the possibility presented itself that part of the butyric acid is oxidised through succinic acid as an intermediary. Malonate might then serve to prevent further oxidation of the succinic acid. No evidence in favour of this view was found on measuring the acid-base change with butyrate and guinea-pig liver, for we found in absence of malonate that  $Q_s$  had the value  $-0.4$ , and in presence of malonate  $-0.2$ . If in the latter case a dibasic acid were formed, and in the former it were oxidised to carbon dioxide and water, the first value of  $Q_s$  would be definitely more negative than the second.

*The effect of poisons on the acetoacetic acid production by rat liver.*

It has already been mentioned (Part II) that in the absence of added substrates rat liver shows an appreciable production of acetoacetic acid,  $Q_a$  having a mean value of  $1.1$ , and it is possible therefore to study the effect of conditions on this "spontaneous" acetoacetic acid production.

The acetoacetic acid production, as already mentioned, is inhibited by benzoate, and it is also inhibited by arsenite. Both substances also inhibit the acetoacetic acid production from added fatty acids.

It occurred to us that, if the "spontaneous" acetoacetic acid production were due to oxidation of fatty acids liberated by hydrolysis of fats or phosphatides, it might be inhibited in a specific manner by substances which inhibit lipase action. We have therefore examined the effects of quinine and atoxyl.

In order to produce inhibitory effects on the acetoacetic acid production from liver slices it was necessary to use very much higher concentrations of these substances than are inhibitory to purified esterase preparations.

It was found (Table VII) that at a concentration of quinine which inhibited the spontaneous acetoacetic acid production, the acetoacetic acid production from added fatty acid was inhibited to about the same extent. On the other hand, with atoxyl (Table VI) the inhibition of acetoacetic acid production from added fatty acid was much less than that in the absence of added fatty acid. The action of atoxyl is therefore much more specific than that of quinine on "spontaneous" acetoacetic acid production.

The effects of quinine and atoxyl on the esterase activity of rat liver were then compared. According to Rona and Lasnitzki [1926], the esterase of tissue slices diffuses into the medium to some extent, and the esterase activity is also dependent on the thickness of the slices. We therefore tried to choose slices of uniform thickness, but the accuracy of these experiments is not great.

In each experiment the poison was present in the manometer vessel from the beginning, and after some time at  $37^\circ$   $0.15$  ml. of tributyrin was added to the  $3.2$  ml. of Ringer's solution in which the tissue slices were being shaken. The tributyrin only dissolved in part, and approximately saturated the Ringer's solution. The rate of gas output was approximately constant for some time, and the rate during this period was used as a measure of the esterase activity.

In one experiment the tissue-slices were removed before adding tributyrin, and the esterase activity of the residual Ringer's solution was measured. (In Tables VIII and IX the esterase activity is stated in terms of the weight of tissue removed.) It was found that the activity in the Ringer's solution was diminished by atoxyl to the same extent as the activity in the presence of tissue slices. This simplifies the interpretation of the other experiments.

Table VI. *Inhibitory effects of atoxyl.*

	% decrease in $Q_{Ac}$	—	80	—	38
4	Conc. atoxyl ( <i>M</i> )	0	0.012	0	0.012
	Conc. decanoate ( <i>M</i> )	0	0	0.0025	0.0025
	$Q_{O_2}$	9.46	5.50	11.81	7.47
	$Q_{Ac}$	1.03	0.24	3.02	1.77
	% decrease in $Q_{Ac}$	—	76	—	41
B. On esterase action.					
Exp.	Ringer's solution $N_2 + 5\% O_2$ . 0.025 <i>M</i> $NaHCO_3$ .				
1	Conc. atoxyl ( <i>M</i> )	0	0.002	0	0.002
		Tissue removed		Tissue present	
	Time when tissue removed (min.)	30		45	
	Time when tributyrin added (min.)	50			
	$Q_{CO_2}^{N_2}$	42	21	164	84
	% inhibition	50		52	
Tissue present. Tributyrin added after 20 min.					
2	Conc. atoxyl ( <i>M</i> )	0	0.003	0.006	0.012
	$Q_{CO_2}^{N_2}$	127	47	52	33
	% inhibition	63		59	74

A comparison of the data in the tables shows that at concentrations of atoxyl and quinine which inhibit acetoacetic acid formation considerably, the esterase activity (measured under our rather arbitrary conditions) is also inhibited. The inhibition by quinine of esterase is not quite so great as that of the acetoacetic acid production, whilst in the case of atoxyl the inhibition of esterase activity is of the same order as that of the spontaneous acetoacetic acid production.

Taking the results altogether, we may conclude that the action of quinine is not connected with an effect on lipase activity.

Atoxyl, on the other hand, probably exerts its effect on the spontaneous acetoacetic acid production principally by depressing lipase activity. For here we have the facts (1) that the effect of atoxyl on "spontaneous" acetoacetic acid production is greater than on  $Q_{Ac}$  with added fatty acids, and the effect is probably therefore of another kind than with quinine, and (2) the effect on esterase action is of the same order as on spontaneous acetoacetic acid production.

Table VII. *Inhibitory effects of quinine.*

	$Q_{O_2}$	10.67	8.43	13.42	8.98
	$Q_{Ac}$	0.91	0.25	3.42	0.65
	% decrease in $Q_{Ac}$	—	73	—	81
B. On esterase action.					
Ringer's solution, $N_2 + 5\% CO_2$ . 0.025 <i>M</i> $NaHCO_3$ .					
Tissue-slices present. Tributyrin added after 25 min. in bath.					
	Conc. quinine ( <i>M</i> )	0	0.002		
	$Q_{CO_2}^2$	125	87		
	% inhibition		30		

We are therefore led to the tentative conclusion that the "spontaneous" acetoacetic acid production is bound up with lipase activity. This in turn makes it probable that the origin of the acetoacetic acid is from fats or phosphatides, which must be hydrolysed before they are accessible to oxidation with production of acetoacetic acid.

As a corollary we should conclude that in the liver the concentration of free fatty acids must be low, since otherwise the liver slices could produce acetoacetic acid for some time even if the lipase were inactive. This conclusion receives some support from the finding of Weber and King [1935] that the salts of fatty acids at low concentrations inhibit liver esterase. Such an inhibitory action means that probably fatty acids cannot accumulate to any great extent.

We have made the assumption in the above arguments that liver esterase behaves in the same manner to inhibitors as does the lipase or phosphatidase responsible for the production of fatty acids in the liver. The arguments can therefore obviously only be suggestive, not conclusive.

#### SUMMARY.

1. Kidney, spleen and testis produce acetoacetic acid in small quantities from fatty acids, but brain gives no measurable production. All these tissues produce acetoacetic acid from *dl*- $\beta$ -hydroxybutyric acid.

2. In the absence of potassium and calcium ions the rate of production of acetoacetic acid from  $\beta$ -hydroxybutyric acid by kidney is highest; this is due to the stimulating action of these ions on the breakdown of acetoacetic acid by kidney.

3. Kidney, spleen, testis and liver destroy acetoacetic acid in presence of oxygen, the last two organs being the least active.

4. Acetoacetic acid is also removed anaerobically by kidney.

5. Sodium malonate increases the rate of spontaneous acetoacetic acid formation by liver (*i.e.* the formation in absence of added fatty acids). Its effects on the respirations of rat and guinea-pig liver are noted. Malonate inhibits the oxidation by the liver of acetic, propionic and butyric acids and also the breakdown of acetoacetic acid.

6. Atoxyl inhibits in a specific manner the spontaneous acetoacetic acid formation by liver; quinine also does so but in a less specific way. The inhibition by atoxyl takes place at those concentrations which inhibit esterase activity of liver, and it is concluded tentatively that the spontaneous formation of acetoacetic acid is due to the oxidation of fatty acids liberated by hydrolysis from fats present in the tissue.

7. The interpretation of the R.Q. of isolated tissues is discussed. If the spontaneous acetoacetic acid formation of rat liver is due to oxidation of fat, it follows that the R.Q. of oxidation of fat by liver is less than 0.7.

# CCLVIII. URIC ACID SYNTHESIS IN PIGEONS. I.

By REGINALD BRETTAUER FISHER.

*From the Department of Biochemistry, University Museum, Oxford.*

*(Received July 25th, 1935.)*

IN this paper and a subsequent one I propose to describe a method for the investigation of the source of carbon for uric acid synthesis in pigeons. As the method comprises (1) the establishment of the normal characteristics of the relation between uric acid excretion and nitrogen intake (or food intake on a uniform diet) of birds allowed to feed freely and (2) the study of the effects of the administration of various compounds containing carbon on the characteristics of this relation, the investigation is best described under these two headings. This paper is therefore concerned with the establishment of the normal relation.

There appear to be no figures in the literature which yield any information concerning this relation in the pigeon, and the published figures for the hen are at variance with one another. Von Knierem [1877] claimed that over 90 % of ingested nitrogen was excreted by hens as uric acid. In these experiments adult birds of 1.0–1.4 kg. were given 20 g. of pearl barley *per diem*, and lost weight steadily throughout the experiment. Pupilli's [1932] data indicate that his hens, receiving 75 g. of maize *per diem*, excreted 28–38 % of ingested nitrogen as uric acid. St John *et al.* [1932] present data which show that normally 50 % of the nitrogen excreted by 11–12 weeks' old chicks is in the form of uric acid. These data suggest that the relation between food intake and uric acid excretion in the hen is either extremely unstable or that it is non-linear.

## METHODS.

Blue-bar homer pigeons were used, and all but two of the animals were cocks. The birds were kept singly in metabolism cages measuring 18 × 15 × 12 in. The excreta were collected on red rubber sheets laid on the metabolism cage trays, and the birds were separated from the rubber by a grid made of a rectangular frame of strip brass, with copper wires stretched across parallel to the shorter side of the frame at intervals of  $\frac{3}{4}$  in.

In the earlier experiments the animals were kept in the laboratory animal house, but it was found to be more convenient to keep them apart in a dark room illuminated by a single 100-watt lamp, controlled by a time-switch. In these circumstances scattering of food and the deposition of excreta in awkward places was eliminated, and it was possible to train the birds rapidly to feed at any convenient hour and to take enough in one feed *per diem* to enable them to maintain constant weight. In the earlier experiments the food-boxes were left *in situ* except on the occasions, at intervals of 24 hours, when they were weighed and refilled if necessary. In the experiments with controlled illumination the boxes were presented to the birds for one hour only at 24-hour intervals. As the birds took at least as much food on the average in these circumstances as when access was completely unrestricted, it is justifiable to say that in all circumstances the birds were allowed to feed freely.

In all the experiments it has been most convenient to carry out analyses on 48-hour samples, but the collection of excreta has been made daily. The

excreta could readily be removed from the rubber sheet if the sheet were laid in a wide V-shaped trough sloping down towards a 500 ml. crystallising dish in which the excreta were collected. The excreta were moistened with 97 % alcohol and scraped off with a blunt knife.

The determinations of uric acid content were made by St John and Johnson's [1931] method, which was originally developed for use with hen excreta. The method does not give uniformly good products when applied to fresh pigeon excreta, but I have found that the extraction of the excreta with hot 97 % alcohol removes the interfering substances without removing any uric acid. The procedure which I have adopted is to extract the 48-hour sample with 100 ml. of 97 % alcohol on a water-bath for 10 min., and to pour off the alcohol through a large folded filter. The moist residue is transferred to a porcelain mortar and ground to uniform fineness. The mass is washed back into the crystallising dish with 97 % alcohol, and the volume of alcohol is made up to approximately 100 ml. Extraction is continued for 10 min. on the water-bath and the alcohol poured off through the filter. Two further similar extractions are made. The residue on the filter is added to that in the dish and the alcohol is removed on the water-bath. The light brown solid can then be submitted to St John and Johnson's procedure.

The following experiments show that this extraction does not affect the uric acid content of the excreta. A mass of fresh excreta is reduced to as uniform a state as possible, and aliquots are subjected to different numbers of alcohol extractions carried out as described above. The solid residues are analysed by the St John and Johnson procedure. The results are given in Table I.

Table I.

Exp.	Extractions	Wt. of excreta g.	Uric acid found	
			Total mg.	mg. per g. excreta
1	3	12.3098	179.5	14.582
	6	11.6381	167.5	14.392
	9	12.5728	182.5	14.515
2	4	21.1012	270.5	12.819
	6	18.9754	241.5	12.727
	8	22.1367	279.5	12.626
	10	20.5876	261.5	12.702

In neither instance is there any sign of decrease in the uric acid content with increase in the number of extractions, and although the variation is rather large (up to 0.9 % from the mean), it is probably accounted for by the difficulties of sampling.

In the early experiments a mixed corn diet, consisting mainly of wheat, maize and dari, was used, but in most of the experiments whole wheat has been used. In each experiment enough of the food for the whole experiment has been stored in a stoppered jar and samples have been taken from time to time for nitrogen estimation by micro-Kjeldahl.

## RESULTS.

In view of the multiplicity of factors which may influence it, it is impossible to estimate with accuracy the interval which is likely to elapse between the ingestion of food and the excretion of the corresponding nitrogen as uric acid. But there are indirect methods which should yield approximately correct figures. For instance, if birds are allowed continuous access to food, and in these circumstances the uric acid excretion per 48-hour period is correlated with the food intake per 48-hour period, in such a way that each food intake period terminates "*t*" hours before the corresponding uric acid excretion period, the correlation

coefficient obtained will be a good index of the truth of the assumption that  $t$  hours approximate to the required interval.

In six out of ten experiments in which this point was tested, with  $t = 24$  hours, correlations were observed which were significantly different from zero. This answer was too equivocal to be satisfactory, and a further series of fifteen experiments was performed, in which food was presented for one hour only each day, and the 24-hour interval between the end of the food intake period and the end of the excretion period was retained. In this series only two of the fifteen experiments exhibited correlations which were not significantly different from zero, and it is therefore justifiable to assume that in these circumstances approximately 24 hours elapse between the ingestion of food and the excretion of the corresponding nitrogen as uric acid. The figures on which this conclusion is based are collected in Table II. It will be realised that they also demonstrate what is implicit in this investigation, that the uric acid excretion does in fact depend directly on the food intake.

Table II.

Exp.	Bird	Diet.	Number of observations	Correlation coefficient

The correlations in heavy type are not significantly different from zero.

The next matter of importance is the linearity of the relation between food intake and uric acid excretion. Unfortunately methods of fitting curved regression lines to data of the sort available here have not been worked out, so that the desirable demonstration, *i.e.* that it is not possible to fit a curved line to the data more closely than a straight line, must be forgone. It is necessary to be content with the demonstration that in those instances in which the correlation is highest, and the relation is therefore least ambiguous, the curve differs negligibly from a straight line. Figs. 1-3 show that this is in fact so.

Finally, it is of interest to see if there is a fundamental similarity in the behaviour of the different birds. Since each regression line passes through the point  $(\bar{x}, \bar{y})$ , where  $\bar{x}$  is the mean food intake observed in the particular experiment, and  $\bar{y}$  is the mean uric acid excretion, it follows that, if the individual experiments yield regression lines which differ only adventitiously, all the points

of the type  $(\bar{x}, \bar{y})$  should lie on or near to a straight line. In order to test this point all the values of  $\bar{x}$  have been reduced to the common measure of mean intake of nitrogen. For ease of interpretation  $\bar{y}$  is expressed as uric acid-nitrogen

Fig. 1. Exp. 10.

Fig. 2. Exp. 15.

Fig. 3. Exp. 18.

excreted. The data for ten experiments in which mixed corn was fed and for fifteen in which whole wheat was fed are given in Table III and Fig. 4. The correlation of  $\bar{y}$  on  $\bar{x}$  calculated from these data is 0.7826. As in a similar set of data a correlation coefficient of 0.49 would be considered to be significantly

Table III.

Fig. 4. ○, mixed corn; ●, whole wheat.

different from zero it is clear that there is an important fundamental similarity between the different birds in respect of this relation. It is justifiable therefore to go to the labour of pooling all the individual observations made in the twenty-five experiments in order to obtain a more precise estimate of this fundamental observation.

As inspection of Fig. 4 reveals that the scatter of the mixed corn points is far greater than that of the whole wheat ones, a circumstance which is probably a direct consequence of the greater heterogeneity of the mixed corn, I have calculated regressions for the two series of experiments separately. The correlation coefficients and the parameters of the regression lines obtained are recorded below:

Experiments 2-11 (mixed corn). 171 observations.

$$\begin{aligned}
 r_{xy} &= 0.76981 \pm 0.0240 \\
 b &= 0.4957 \pm 0.0316 \\
 A &= 16.98 \pm 19.58.
 \end{aligned}$$

Experiments 12-26 (whole wheat). 263 observations.

$$\begin{aligned} r_{xy} &= 0.85875 \pm 0.0162 \\ b &= 0.4195 \pm 0.0316 \\ A &= 25.80 \pm 9.55. \end{aligned}$$

$r_{xy}$  is the correlation coefficient.  $A$  and  $b$  are the parameters of the regression line:  $Y = bx - A$ , where  $Y$  = mg. uric acid-nitrogen excreted per 48 hours, and  $x$  = mg. nitrogen ingested per 48 hours.

The considerable similarity between the two series, which is shown also by Fig. 4, is further evidence of the fundamental similarity in behaviour of all the birds.

As a corollary to this demonstration of the general character of the relation it is probably safe to state that adult blue-bar homer pigeons excrete 42-50 % of ingested nitrogen as uric acid, and that the most probable level of endogenous uric acid excretion is 17-26 mg. of uric acid-nitrogen per 48 hours, or approximately 25-40 mg. of uric acid *per diem*. This is of the order of 5-10 % of the daily excretion of uric acid.

#### SUMMARY.

1. Approximately 24 hours elapse between the ingestion of food nitrogen by blue-bar homer pigeons and the excretion of the corresponding uric acid.
2. The relation between the amount of nitrogen ingested and the amount of uric acid excreted is linear.
3. The relation between these two variables is fundamentally the same in all the instances examined.
4. Calculations based on 171 observations on birds fed with mixed corn and 263 observations on birds fed with whole wheat lead to the conclusion that 42-50 % of ingested nitrogen is excreted as uric acid, and that in addition a constant amount of 25-40 mg. of uric acid is excreted *per diem*.

I am very grateful to Prof. Peters for his interest in and encouragement of this work, to Prof. R. A. Fisher for invaluable advice on statistical matters, and to my colleagues for aid of various kinds.

## CCLIX. URIC ACID SYNTHESIS IN PIGEONS. II.

By REGINALD BRETTAUER FISHER.

*From the Department of Biochemistry, University Museum, Oxford.*

*(Received July 25th, 1935.)*

THE demonstration by von Knierem [1877] and von Schroeder [1878] that the nitrogen of amino-acids and of ammonium salts can be converted into uric acid in the organism of the bird, and Minkowski's [1886] demonstration that after hepatectomy in the goose the uric acid content of the urine fell to a very low value and large amounts of dextrorotatory lactate were excreted, together with the tacit assumption of an underlying similarity in the processes of ammonia detoxication in the bird and mammal, ultimately led to the attractive hypothesis of the formation of uric acid by the condensation of one molecule of lactic acid, or of a related compound, with two urea molecules.

Most investigations of this synthesis have been based on this hypothesis. For instance Wiener [1902] believed that he could show that a very large number of compounds related to lactic acid would produce an increase in the uric acid excretion of hens given large daily doses of urea, up to 100 % of the compound administered being recovered as uric acid. However, a statistical examination of some of Wiener's results renders his conclusions very doubtful (see the Appendix to this paper). Again Ascoli and his colleagues [Ascoli, 1898; Ascoli and Izar, 1909; Bezzola *et al.*, 1909; Izar, 1910, 1, 2; 1911; Preti, 1909], in an elaborate series of investigations, claim to have demonstrated uric acid synthesis from non-purine precursors in mammalian and avian livers and have also claimed that by their technique the synthesis of uric acid from dialuric acid and urea can be demonstrated in liver "brei". But attempts to repeat their fundamental observations made by Spiers [1915] and by Calvery [1927] have failed.

Pupilli [1928; 1930] has claimed recently that in the hen urea is conjugated with most of the compounds used by Wiener to yield uric acid, and that the same process can be observed in liver powder. However, he relies on an iodimetric method of estimating uric acid due to Ganassini [1914], which does not seem to be very specific, and his results are at variance with those of Clementi [1930], who claims that injected urea can be recovered quantitatively from the excreta of birds, whether or no salts of such acids as pyruvic and malonic acid are simultaneously administered. Torrisi and Torrisi [1931] and Russo and Cuscuná [1931] have published work in support of Clementi's conclusions. Torrisi and Torrisi appear to show, in addition, that the administration of pyruvic and malonic acids has no effect on uric acid excretion by the hen.

Three investigations which do not rest on the original hypothesis show considerable accord with one another. Kowaleski and Salaskin [1901] claimed that they had shown that when a goose liver was perfused with blood uric acid was added to the blood, and that the extent of this addition was greatly increased if ammonium lactate were added, a finding which appears to indicate, in view of the continued failure to obtain urea synthesis in isolated perfused liver preparations, that urea is not a precursor of uric acid. Schuler and Reindel [1933, 1, 2] and Krebs and Benzinger [1933] have shown, independently, that the

kidney, as well as the liver, may play an important part in the synthesis of uric acid in some birds, and the latter workers, by utilising this discovery, have been able to show convincingly that ammonia can act as a source of nitrogen for uric acid synthesis and that urea cannot.

Krebs and Benzinger, working with tissue slices, took the opportunity of testing a number of compounds as sources of carbon for the synthesis. Of those tested, only *dl*-lactate, pyruvate and glucose increased the rate of uric acid synthesis of their preparation, and these increases in rate were observed only when tissues from a starving animal were used. In view of the observation of Krebs and Henseleit [1933] that the same substances increased the rate of urea synthesis in mammalian liver slices, *i.e.* accelerated a synthesis in which they did not participate, it seemed very likely that, in both instances, the acceleration occurred by way of an improvement in the nutritional state of the tissue.

Whereas, then, it is reasonably certain that the source of the nitrogen for the synthesis is ammonia, and that urea is not an intermediary, there is very little positive information concerning the source of carbon, as the following table shows:

*Reputed sources of carbon for uric acid synthesis.*

Wiener's results are statistically unsound, as I shall show later. Neglecting them, it will be seen that, in every instance but one in which more than one investigation has been made, there is disagreement as to the ability of the substance in question to increase uric acid production. The one instance is that of racemic lactate, and it seems therefore that the most important question remaining to be answered in connection with this synthesis is: does lactic acid stimulate the synthetic mechanism or does it participate directly in the synthesis?

The investigation to be described in this paper is an attempt to answer this question. The general plan of the investigation is that the relation between food intake and uric acid excretion of a pigeon is determined, as described in the foregoing paper [Fisher, R. B., 1935], and then the same relation is redetermined whilst the pigeon is receiving a constant daily dose of sodium lactate. As there is no restriction on the amount of food eaten by the pigeon, and as the body weight remains constant within very narrow limits, there is no reason to suppose that the lactate administered can improve the nutritional state of any tissue. Further, the lactate administered has never been more than the equivalent of 100 mg. of the free acid *per diem*, so that its energy equivalent has not exceeded approximately 360 g. cals. On the basis of Benedict and Riddle's [1929] figures, the

birds used in these experiments should dissipate between 50,000 and 70,000 g. cals. *per diem*, so that the lactate fed could supply at most 0.7 % of the bird's daily energy requirement.

Since, however, the base fed with the lactate may produce an effect similar to that which it would produce in a mammal, namely, sparing action on ammonia production by the kidney, it is possible that nitrogen will be made more readily available for further uric acid synthesis. This point can be tested by feeding equivalent amounts of sodium bicarbonate or sodium acetate, but a more elegant and more complete control would be obtained if it could be shown that one of the optical isomerides of lactic acid, fed as the sodium salt, increased uric acid excretion, whereas the other did not do so.

Experiments of this type have been performed, in which one of a pair of birds received sodium *l*-(+)-lactate and the other received sodium *d*-(-)-lactate. A period of twelve days was arbitrarily chosen for the lactate administration. It seemed possible that a gradual adaptation of carbohydrate metabolic mechanisms might take place during prolonged administration of lactate, and it was decided therefore that the period of lactate administration should be as short as was consistent with the establishment during the period of a definite regression of uric acid excretion on food intake. The lactate was given by pipette once every 24 hours, at the end of the feeding period, and the excreta were analysed in 48-hour samples as in the previous work.

The lactate solutions used were prepared from the zinc ammonium salts, and the final solutions were examined polarimetrically and tested for the presence of ammonia. In no instance was racemisation detected or ammonia found in the solution.

Typical results are presented in Figs. 1-4. The hollow circles represent results obtained without lactate feeding: the full circles represent results obtained during lactate feeding. It is obvious that in Figs. 1 and 3 the uric acid excretion at a given food intake is constantly above the normal level, whereas in Figs. 2 and 4 there is no constant difference between normal and lactate results.

Since it is also obvious that the differences between the results obtained in normal periods and during lactate feeding cannot be expressed simply, it is necessary to consider at this point the probable nature of the different possible actions of lactate on uric acid excretion.

In the first place, it has been shown that *l*-(+)-lactate increases the uric acid excretion at a given food intake, whereas *d*-(-)-lactate does not, so that it is no longer necessary to consider the possibility that the effect of lactate is due to the base administered. (There is no reason to suppose that the birds would have any difficulty in metabolising completely the amounts of *d*-(-)-lactate administered, since these never exceeded 100 mg. of the free acid *per diem*.)

The possibilities left are (1) a specific stimulant action of lactate on the synthetic mechanism, and (2) a participation of lactate in the synthesis. Other possibilities, such as alterations of excretion of uric acid rather than its synthesis, are rendered unlikely by the persistence of the effect over a period of twelve days.

In view of the fact that the relation between nitrogen intake and uric acid excretion is linear (see previous paper), it is unlikely that the synthetic mechanism is saturated with respect to nitrogen. Yet only about 50 % of exogenous nitrogen is excreted as uric acid. Many types of explanation of this fact might be devised, but it is at least possible that this failure to convert more nitrogen into uric acid is in some measure due to inadequate supply of the source of carbon. If we consider the possibility that the source of carbon for the synthesis may be com-

Fig. 1.

peted for by the synthetic mechanism and by some other metabolic mechanism which need not be specified, then it is easy to see how, in normal circumstances, the extent of the conversion of exogenous nitrogen into uric acid may be so small. If in these circumstances the synthetic mechanism is activated by some regularly presented stimulant, then the proportion of nitrogen presented to it which will be converted into uric acid will be increased. On the same hypothesis, if an excess of the source of carbon be regularly presented in such a way that the relative activities of the synthetic and competing mechanisms are unaltered, then a constant excess of uric acid over the normal for the particular food intake should be excreted, and this amount should never reach the theoretical maximum calculated on the basis of the complete conversion of the administered substance.

In other words, if 
$$Y = bx + A$$

represents the relation between food intake and uric acid intake, where  $Y$  = food intake per 48 hours,  $x$  = uric acid excretion per 48 hours, and  $b$  and  $A$  are constants, it follows that the administration of lactate, if it stimulate the synthetic mechanism, will bring about an increase in  $b$ , whilst if it participate in the synthesis it will bring about an increase in  $A$ .

From these considerations it is obvious that the differences between the normal and lactate results shown in Figs. 1-4 can best be expressed in terms of the parameters of the regression lines. Since the samples of data available are small, and since the estimates of those parameters which are obtained will be approximations, the following procedure has been used to determine how far the observed differences are significant ones.

In the first place the parameters of the regression lines for the series of data obtained during normal feeding and for the series obtained during lactate administration have been calculated for each bird. In the instance of the data of Fig. 1 the regression lines are:

$$Y = 17.6988x - 4.34 \dots \text{normal}$$

$$Y = 21.2925x - 48.51 \dots \text{lactate.}$$

The standard error of the difference between the two estimates of  $b$  can be calculated [R. A. Fisher, 1932, p. 126]. In this instance it is 8.272. The ratio of the observed difference between the two estimates of  $b$  to the standard error of that difference (*i.e.* here  $(21.2925 - 17.6988)/8.272 = 0.511/1$ ) constitutes the statistic  $t$ . It is possible to read off from the appropriate tables [R. A. Fisher, 1932, p. 151] the probability that, in two such samples as these, a difference, of the magnitude observed, between the values of  $b$  could arise by chance even if the samples were random ones from the same population. The less the probability of such a difference, the greater the value of  $t$ .

In this instance the value of  $t$  is 0.511. For a set of data possessing, as this one does, 21 degrees of freedom,  $t = 0.532$  when  $P = 0.6$ . In other words there are rather more than six chances out of ten of obtaining differences in  $b$  of the observed magnitude between two series of data from the same normal bird, so that lactate administration cannot be said to have influenced the value of  $b$  significantly.

The next step is to determine the significance of the differences between the values of  $A$ . The first step, since we are assuming the values of  $b$  to be the same within experimental limits, is to obtain a pooled estimate of  $b$  from the two series of data and to calculate corresponding new values of  $A$ . This procedure should reduce the effect of chance variations in the value of  $b$  on the estimates of  $A$ . In the instance under consideration, this procedure gives:

$$Y = 17.8320x - 8.99 \dots \text{normal}$$

$$Y = 17.8320x + 94.15 \dots \text{lactate.}$$

The standard error of the difference between the estimates of  $A$  is then calculated. (It should be noted that  $A$  differs from the constant " $a$ " discussed by R. A. Fisher:  $A = a - b\bar{x}$ , and in consequence  $A_L - A_N = (a_L - a_N) - b(\bar{x}_L - \bar{x}_N)$ , and  $V_{(A_L - A_N)} = V_{(a_L - a_N)} + (x_L - \bar{x}_N)^2 \cdot V_b \dots$  where  $V$  signifies the variance of the subscribed quantity.) The standard error in this instance is 29.12, and the difference in the estimates of  $A$  is 103.14. The value of  $t$  is therefore 3.542. With 21 degrees of freedom,  $t$  is 2.831 for  $P = 0.01$ , and therefore there is less than one chance in a hundred of observing such a difference between samples drawn from the same population. That is, the samples are drawn from different populations, and lactate does cause a significant increase in the value of  $A$ .

The five other sets of data have been examined in the same fashion, and the results of the examination are presented in the table below:

Exp.	$b_L - b_N$	S.E. of diff.	$P_b$	$A_L - A_N$	S.E. of diff.	$P_A$
D. 50.617	4.231	8.272	0.60	103.14	29.12	0.0002
D. 75.294	- 3.361	5.590	0.56	89.09	53.69	0.11
D. 100.617	- 7.856	15.928	0.65	107.73	39.08	0.015
L. 50.271	- 14.729	6.323	0.032	- 86.81	42.54	0.055
L. 75.617	- 12.534	12.927	0.34	19.15	153.36	0.90
L. 100.2000	- 2.353	8.149	0.80	15.02	90.63	0.90

Under the heading "Exp." the designation D. 50.617 means that in this experiment bird 617 has been receiving 50 mg. *per diem* of dextrorotatory lactate.

This table merits discussion in some detail. In the first place it will be seen that in every instance but one the apparent effect of lactate administration on the value of  $b$  is a reduction. However, the standard error of the estimate of the difference between the normal and lactate values of  $b$  (column three) is so large that none of these changes is significant. The general conclusion must be that there is certainly no increase in  $b$  following lactate administration, but that there may be a decrease although the errors of estimation in the present data are such that the observed decreases are not significant.

If, in point of fact, there is a decrease in  $b$ , then the estimates of the difference in  $A$  are all too low, but there is not the material to assess the magnitude of this possible effect. With the exception of the first value obtained for laevorotatory lactate the values of  $A$  are strikingly uniform within the two classes. This part of the table is self-explanatory, and it will be seen that, although in one instance the rise in  $A$  following dextrorotatory lactate does attain the level of significance, there is in this instance a very large value of the standard error. The only instance of approach to significant level in the laevorotatory series is an instance of a fall in  $A$  following lactate and need not be considered further. The last point in connection with these results is that unfortunately the standard errors of the differences in the last two instances in the laevorotatory series are very high indeed and it might be suspected that this accident was responsible for the high values of  $P$ . However, even were the standard error in either instance to be reduced to 30 the value of  $P$  would not fall below 0.54; there would still be 54 chances in 100 of observing such a difference between two samples of a uniform population having that variance.

Thus there can be very little doubt that the administration of sodium  $d$ -(-)lactate does not bring about an increase in either of the parameters of the regression line, whereas the administration of sodium  $l$ -(+)lactate brings about an increase in  $A$  but no increase in  $b$ .

That is, the regular administration of a constant dose of sodium  $l$ -(+)lactate tends to produce a constant increase in uric acid output, irrespective of the food

intake. Furthermore this increase represents a physiologically reasonable conversion of the lactate into uric acid. In the three experiments quoted in the table above the values of  $(A_L - A_N)$  represent 55.3, 28.4 and 28.9 % conversion respectively.

If the theoretical discussion earlier in this paper of the physiological significance of changes in the parameters of the regression line is valid, it follows that *l*-(+)-lactate can participate in uric acid synthesis in pigeons, whereas *d*-(-)-lactate cannot.

#### SUMMARY.

Sodium *d*-(-)-lactate, in daily doses containing from 50 to 100 mg. of the free acid, has no effect on the uric acid excretion of homer pigeons.

Sodium *l*-(+)-lactate, in similar amounts, increases the uric acid excretion significantly. The nature of this increase is analysed, and reasons are given for regarding it as indicative of the direct participation of *l*-(+)-lactic acid in the synthetic process.

I wish to express my thanks to Prof. Peters for his encouragement, to Prof. R. A. Fisher for his help with statistical difficulties, and to the Distillers Company's Laboratories for the gift of generous quantities of zinc ammonium lactates.

#### APPENDIX.

*The statistical adequacy of Wiener's investigations of uric acid synthesis in hens.*

Since Wiener's investigations form the cornerstone supporting the urea-conjugation hypothesis of uric acid synthesis, it is a matter of some importance if it can be shown that his results are statistically inadequate to sustain his claims.

The daily doses are given in terms of the free acid although the acid was administered as the sodium salt.

I have chosen the results obtained with lactate, malonate and tartronate for examination. The lactate series is the most numerous and should give the least equivocal answer. The malonate and tartronate results are chosen because Wiener claimed 100% conversion of these substances.

Wiener's method was to give hens a constant daily dose of urea and to determine the uric acid excretion in three successive 24-hour periods. The test-substance, lactate, malonate or tartronate, was then given in a constant daily dose, in addition to the urea, and the uric acid excretion in three successive 24-hour periods was again determined. The results obtained when lactate was fed are reproduced in the above table (p. 2204).

The method used for the examination of these results is that given by R. A. Fisher [1932, p. 114]. The essential steps are the determination of the variance, *i.e.* the value of  $S(x - \bar{x})^2$ , for each group of results, and the derivation from this of an estimate of the standard error of the difference of any two of the means. The estimate of the standard error, divided into the observed difference between the means in question, gives a value of *t* from which the probability of a difference of the magnitude observed occurring between samples of the same population can be estimated. If the means compared are derived respectively from series with and without lactate feeding, a high probability will signify that the series with lactate feeding belongs to the same population as the series without lactate feeding, that is, that lactate has no significant influence on uric acid excretion.

The essential results are collected in the table below:

Bird	Lactate	Diff. of means	Standard error	<i>t</i>
(7)A	<i>L</i> (- ) lactate	0.06	0.13	0.492
(4)C	<i>dl</i> -lactate	0.21	0.42	0.502
	<i>L</i> (- ) lactate	0.17	0.45	0.378
(4)D	<i>dl</i> -lactate	0.72	0.49	1.433
	<i>L</i> (- ) lactate	0.17	0.38	0.455
(4)E	<i>dl</i> -lactate	0.36	0.27	1.355
	<i>L</i> (- ) lactate	0.45	0.40	1.129

The figures in brackets in front of the letters designating the birds indicate the number of degrees of freedom of the data. The "Diff. of means" column shows the difference between the mean of the normal results for that bird and the mean of the results obtained during lactate feeding.

As, for 7 degrees of freedom,  $t=0.543$  when  $P=0.6$ , and, for 4 degrees of freedom,  $t=1.533$  when  $P=0.2$ , it follows that in the most favourable instance there is still more than one chance in five of the observed difference arising by chance between two samples from the same population.

However, it might be objected that the uniformly positive character of the change when lactate is fed must mean that there is a true rise in uric acid excretion as the result of lactate feeding, even though the rise is not significant in individual instances. This point is best tested by considering the results obtained with birds C, D and E, which should all be comparable. The average of the difference of means (see table) for *dl*-lactate for these three birds is 0.430, and the standard error of this average is 0.151. In order to test whether the average is significantly different from zero,  $t=0.430/0.151$  is calculated, the answer being 2.842. As the data possess only 2 degrees of freedom,  $t=2.920$  when  $P=0.1$ , and in consequence the average difference cannot be said to differ significantly from zero. When the results obtained with *L*(+)-lactate are treated similarly a value 2.817 is obtained for *t*. That is, the variation in the observed mean rise in uric acid excretion is so great that there is at least one

chance in ten of obtaining a mean difference of zero in a series of three experiments carried out in the same manner as Wiener's.

The experimental data for malonic acid and tartronic acid are presented in the following table:

<i>Uric acid excretion.</i>			
(g. per 24 hours.)			
Bird	No addition	Malonate or tartronate	Daily dose
A	1.84		
	1.58		
	1.40	2.34	0.75 g. malonic acid
		1.72	
	1.61	1.61	
	1.61		
F	1.64		
	3.63	4.39	1.5 g. malonic acid
	3.17	3.63	
H	2.56	3.16	
	2.38	3.51	1.23 g. tartronic acid
	2.50	2.56	
	2.51	2.48	

The results of statistical examination of these results can be expressed very briefly: for A there are 7 degrees of freedom, and  $t = 1.621$ . When  $P = 0.1$ ,  $t = 1.895$ . For F and H there are 4 degrees of freedom and the respective values of  $t$  are 1.281 and 1.160. When  $P = 0.2$ ,  $t = 1.530$ . It follows that none of these differences is significant.

In conclusion, it is interesting to note the frequency with which the uric acid excretion in the first 24-hour period of lactate, malonate or tartronate administration shows a very sharp rise, which is followed in the subsequent periods by a fall which may be so great that in the third period the uric acid excreted is less than in any of the normal periods. This suggests strongly that in Wiener's work what was being observed was a washing out of urates, probably due to the diuretic effect of large amounts of the salts administered, followed by a corresponding retention of urates in the later periods. It seems very probable that the apparent increases observed would not have been obtained if the period of administration of lactate *etc.*, had been doubled.

# CCLX. THE OXYTOCIC HORMONE OF THE POSTERIOR LOBE OF THE PITUITARY GLAND. VII.

## SECTION A. ULTRAVIOLET ABSORPTION SPECTRA.

By JOHN MASSON GULLAND  
AND NATHANIEL SAMPSON LUCAS.

## SECTIONS B AND C. ADSORPTION AND ELECTRODIALYSIS.

By MAVIS FREEMAN,<sup>1</sup> JOHN MASSON GULLAND  
AND SYDNEY STEWART RANDALL.<sup>2</sup>

*From the Biochemical Department, Lister Institute, London, S.W. 1.*

*(Received July 12th, 1935.)*

## SECTION A. ULTRAVIOLET ABSORPTION SPECTRA.

FROM investigations of the absorption of ultraviolet light by commercial extracts of the posterior lobe, Graubner [1928] concluded that the hormone molecule plays an essential (*wesentlich*) part in the absorption, basing his views on a supposed correlation of the oxytocic activities with the amount of absorption. In our opinion, such correlation was unreliable owing to the very small quantity of active material which can have been present in these extracts as compared with the amounts of inactive substances. The question has therefore been studied anew.

Measurements of the ultraviolet absorption spectra of purified hormone solutions have not demonstrated relationships either between the values of extinction coefficients and the solid content of the solutions (Fig. 1) or between the amount of absorption and the number of oxytocic units present (Table I). Moreover, when the spectra of a hormone solution were measured before and after electrodialysis at  $p_H$  11 (p. 2218), the initial solution showed a spectrum with a pronounced peak at  $274m\mu$ , whereas the hormone solution after treatment exhibited merely a general adsorption.

It seems probable, therefore, that the amount of absorption is chiefly determined by the presence of variable quantities of absorptive, but non-oxytocic, substances in the extracts and that these are also responsible for the peak at about  $274m\mu$  which is shown by some hormone solutions.

A consideration of the shapes of the absorption curves now recorded, and to some extent also of those of Graubner, suggests strongly that these concomitant substances may be peptide in character; this conclusion is in harmony with the observation, based on qualitative chemical tests, that posterior lobe extracts contain proteoses and possibly peptones [Abel and Pincoffs, 1917].

<sup>1</sup> Travelling Fellow of the Victorian Women Graduates Association.

<sup>2</sup> Lister Institute Research Student in Biochemistry.

In a comparison of the ultraviolet absorption spectra of the extracts (Figs. 1 and 2) with those of proteoses and peptones (Fig. 3), the following similarities between the two groups are apparent:

(1) The general resemblance of the shapes and wave-lengths of the absorption spectra curves.

(2) The presence in acid solutions of flattened peaks with centres at about  $274m\mu$  but sometimes stretching towards shorter wave-length.

Fig. 1. Hormone solutions at  $pH$  3.5-3.7.  $L_1$   $\square$ - $\square$ ;  $L_2$   $\circ$ - $\circ$ ;  
B  $\Delta$   $\Delta$ ;  $K_3$   $\times$   $\times$ ;  $K_4$   $\bullet$ - $\bullet$ .

Table I.

Solution	Solid mg. per ml.	Units per ml.	Units per mg.	$E$ 274-5 $m\mu$	Absorption 274-5 $m\mu$
$L_1$	7.4	160	21.5	6.1	4.3
$L_2$	1.1	270	245.0	45.4	1.0
B	5.6	300	53.5	26.6	14.0
$K_3$	3.6	900	250.0	22.2	8.0
$K_4$	5.3	1000	188.0	22.7	12.0

(3) The presence in acid solutions of wide troughs with centres at about  $250m\mu$  but sometimes extending towards longer wave-lengths.

(4) The filling of this trough as the alkalinity increases.

(5) The disappearance of this trough in alkaline solutions in some cases, so that peak and trough become merged into a wide plateau.

(6) A shift towards longer wave-length and a tendency for the extinction coefficients to increase, both in alkaline solutions.

The spectra of hormone solutions which had been deprived of their oxytocic activity with alkali resembled the spectra of authentic proteoses and peptones in alkaline media.

It was therefore concluded on these grounds also that the ultraviolet absorption spectra of the hormone solutions at present available are not intimately connected with the presence of the hormone molecule but are a property of peptide substances which accompany it.

### EXPERIMENTAL.

#### *Comparison of the absorption spectra of hormone solutions.*

A Hilger spectrograph (Type E3) and sector photometer were used to measure the absorptions. The solutions were "Kamm" solutions (for definition, see Gulland and Newton [1932]) prepared as described by Kamm *et al.* [1928].

The measurements, made under comparable conditions at  $p_H$  3.5–3.7, are summarised in Table I. In Figs. 1, 2 and 3 and Table I, the extinction coefficients are calculated on the basis of 1% solutions of the proteoses, peptones or the residues of hormone solutions, dried at 110°, and at the customary thickness of 1 cm.

## SECTIONS B AND C.

The aim of these experiments, purification of the hormone, has not been achieved, since preparations assaying about 260 oxytomic units per mg. of solid represent the limit of purification which we have reached. Nevertheless, this publication is made because a variety of novel points have been brought to light and also because it records a fully investigated scheme of attack, based on the observation in Section A that the substances which accompany the hormone in purified extracts are peptide compounds of relatively low molecular weight.

### B. ADSORPTION EXPERIMENTS.

1. *Various adsorbents.* The results of a series of experiments on the adsorption of the hormone from a partially purified solution are summarised in Table II. They offer little prospect of extensive purification of the hormone by

Table II. *Effect of adsorbents.*

means of these adsorbents acting alone, because in general those reagents which did not adsorb the active material failed to remove appreciable amounts of solid, whereas elution of the fuller's earth adsorbate with ammonia liberated relatively large quantities of inorganic material in addition to the active substance.

(2) *Adsorption on norite.* The use of norite as an adsorbent was studied by Gulland and Newton [1932], but it was desirable to repeat some of their observations in different circumstances and to attempt to apply the adsorption to the purification of hormone solutions.

The norite was extracted repeatedly with hot 20 % hydrochloric acid, washed with distilled water, dried, extracted twice with silica-distilled glacial acetic acid and washed with silica-distilled water. 100 mg. of the final sample yielded 0.08 mg. of solid in a blank experiment (see below).

In all experiments throughout this paper where determinations of weight were made the acetic acid and water used were distilled and collected in silica apparatus and contained no weighable residue when considerable volumes were evaporated. In alkaline experiments, where ammonia had been used during the adsorption, the norite was freed from ammonia, before being eluted, by being heated at 40° for 30 min. under reduced pressure. This does not diminish the activity. In the other experiments, ordinary reagents were used. Solids were estimated by evaporation of the solutions and drying of the residues to constant weight at 100° in a current of dust-free air.

Adsorption was effected by shaking frequently mixtures of norite, hormone solutions and buffer or diluting liquid (6 ml.) at 0°. The norite was collected, washed with water (10 ml.) which removed no activity, dried and eluted at room temperature. The resulting eluates were concentrated under reduced pressure below 40°.

The results are summarised in Tables III and IV. Confirmation has been obtained of the observation of Gulland and Newton [1932] that norite adsorbs

Table III. *Norite adsorptions. Activity experiments.*

all the active material from alkaline Kamm solutions and at  $p_H$  2, and that most of the activity may be eluted by acetic acid, but these facts cannot be used to effect further purification than that already recorded because the percentage recovery of solid is slightly higher than the percentage recovery of activity.

(3) *Use of norite and fuller's earth in purification.* Attempts were made to purify the hormone in Kamm solutions or in whole extracts of posterior lobe

a) by successive adsorptions with small quantities of norite at  $p_H$  11; (b) by successive adsorptions with norite at  $p_H$  6 and 11; (c) by adsorption on fuller's earth, elution and re-adsorption on norite. The purifications effected, however, were not sufficiently marked to warrant detailed descriptions, and in the case of whole extracts of posterior lobe the concentration factors ranged from 10 to 20.

The following is a description of an experiment in which adsorption of the hormone on norite, preceded by treatment of the solution with fuller's earth, replaced the customary concentration of posterior lobe extracts under reduced pressure and adsorption of the active material as a protein-ammonium sulphate precipitate. This concentration is troublesome and time-consuming owing to frothing of the solution and to the relatively low temperature at which the distillation must be made (below  $40^\circ$ ), and in our hands extraction of the protein-ammonium sulphate precipitate with acetic acid has frequently failed to remove all the active material from the precipitate. The procedure now outlined is therefore of value.

Dried powdered posterior lobe powder (10 g., 15,000 units) was extracted with 0.25% acetic acid (1 litre) for 30 min. on a boiling water-bath, the solid was collected and re-extracted with 0.25% acetic acid (100 ml.). The combined extracts were cooled to  $3^\circ$ , brought to  $p_H$  11 with sodium hydroxide and treated with (Surrey yellow) fuller's earth (5 g.). 15 min. later, the solid was removed by filtration and washed with water (B), and norite (6 g.) was added to the filtrate at  $5^\circ$ . 45 min. later, the norite was collected and washed with water (600 ml.), and the filtrate was treated with norite (A) (2 g.) for 45 min. at  $5^\circ$ . The activity remaining in the filtrate from this adsorption was assayed (C).

The norite fractions were eluted with acetic acid and the following account applies to the first norite fraction. It was eluted twice with glacial acetic acid (150 ml. for the first elution, 50 ml. for the second) and washed with water (50 ml.) and the combined filtrate and washings were evaporated to dryness at  $35-40^\circ$  under reduced pressure. The residual solid was dissolved in glacial acetic acid (20 ml.) at  $40^\circ$  and precipitated with dry ether (50 ml.). The precipitate was re-extracted and re-precipitated in the same way, and the resulting solid (D) was washed with ether and dried over phosphoric oxide. The united ether-acetic acid solutions were filtered and mixed in succession with water (0.8 ml.) and with light petroleum (280 ml.).

The solution was decanted from the gum (E) which had separated overnight and deposited a second gummy precipitate (F) during the subsequent 24 hours. These precipitates were washed with light petroleum and dissolved in water and the solutions were brought to  $p_H$  3 with acetic acid.

Assays of activity and determinations of weight of solid were made at suitable stages and are recorded below.

Fraction	Weight mg.	Oxytocic units	Units/mg.
First precipitate (E)	49.2	7,500	152
Second precipitate (F)	7.40	830	112
Second norite fraction (A)	—	320	—
Filtrate from second norite adsorption (C)	—	120	—
Washings from first norite adsorption (B)	—	40	—
Solid dried over $P_2O_5$ (D)	350	2,960	—
		<u>11,770</u>	

We are greatly indebted to Prof. J. H. Burn who estimated the pressor activity of the first precipitate as being 13% of the oxytocic activity.

## C. DIALYSIS EXPERIMENTS.

It has frequently been suggested that the hormone is a base, and the acceptance of this view is encouraged by its susceptibility to attack by nitrous acid [Gulland, 1933] and by the present observation that the activity is destroyed when acetylation is effected under mild conditions.

Section A shows that some of the substances which accompany the hormone in whole extracts of posterior lobe or in purified solutions are peptide in character—probably resembling proteoses or peptones.

The numerous records of the passage of the active material through dialysing membranes indicate that the molecular size of the hormone is small, and it has now been shown that the hormone and the accompanying material not only pass through cellophane at the same rate but also leave little undialysable residue. The molecular size of the accompanying material is therefore also not large.

On the assumptions, therefore, that the hormone is predominantly basic in character and that the concomitant substances are ampholytic, it is theoretically possible to effect a separation by electrodialysis, provided that the active material is not adsorbed on the ampholytes under the experimental conditions. A series of experiments was therefore made on the cataphoresis of hormone solutions in a three-compartment cell under conditions which varied only as regards the  $p_H$  value of the centre compartment containing the hormone at the beginning of the experiment (Table V). Fig. 4 shows the effect of changes in the  $p_H$  value of the centre compartment on the number of units remaining in it after electrodialysis had proceeded for a standard time.

The hormone did not migrate to the anode under any conditions, and as the  $p_H$  values investigated ranged from 1.6 to 12.5, it must be concluded either that the hormone is not an ampholyte and does not contain a "free" carboxyl group, or that throughout the alkaline range the hormone is adsorbed on basic, non-ampholytic material. Experiments are in progress to determine this point.

At  $p_H$  values more alkaline than  $p_H$  8.5 the hormone did not migrate, whereas it behaved as a cation at reactions more acid than  $p_H$  6.5. Between these values the curve of Fig. 4 may be an approximate ionisation curve having  $p_K$  7.5. Discussion of the theoretical implications of these facts is postponed until further information is available on the question of the adsorption of the hormone by basic substances (see above).

It was then shown by comparative experiments *ad hoc* that the passage of the hormone through the cellophane membrane is essentially due to the passage of the current and is not the consequence of simple diffusion.

Disregarding temporarily, therefore, the theoretical significance of these experiments, the following practical results are evident. First, at  $p_H$  values corresponding to the probable isoelectric points of the proteoses in the acid  $p_H$  range the hormone migrates into the cathode compartment.

Second, the hormone remains in the centre compartment at alkaline reac-

Fig. 4. Cataphoresis of oxytocic hormone solutions. Solution  $K_2$  ○—○; solution  $K_3/10$  ●—●; solution  $K_3D/10$  ×—×.

tions, when the proteose molecules, as anions, should migrate into the anode compartment.

The straightforward electrodialysis of hormone solutions at acid reactions is not practicable as a method of fractionation, because the hormone molecule undergoes reduction at the cathode, with consequent diminution of the activity, which cannot be completely or permanently regained [Gulland and Randall, 1935].

A number of electrodialysis experiments at acid reactions, designed to obviate this difficulty, are described in the experimental section, and studies were also made of electrodialyses at alkaline reactions, in which the hormone did not migrate and was subsequently adsorbed on norite. In this latter connection it was shown for comparative purposes that the proteoses and peptones of "Savory and Moore's peptone" migrated into the anode compartment of the same apparatus from a solution maintained at  $p_H$  10.

The experiments outlined above were unsuccessful in purifying the hormone; in fact, the ratio of activity/solid invariably fell as a result of the dialyses. This was probably due in part to reduction of the hormone molecule at the cathode and in part to destruction of the hormone in the alkaline solutions, for it has been observed that removal of proteose-like material by electrodialysis greatly decreases the stability of the hormone towards alkalis. It is clear that electrodialysis can be used to eliminate inactive substances from hormone solutions, and that the method could be used as a means of purification if the hormone could be protected from simultaneous destruction, but in our opinion the decreased stability of the purified hormone does not strengthen the probability of its isolation in pure state.

Finally, a single attempt was made to separate the oxytocic and pressor substances by electrodialysis at an alkaline reaction. This was unsuccessful because neither hormone migrated to any marked extent. Presumably the pressor hormone is either basic or was adsorbed on basic substances.

## EXPERIMENTAL.

### *Action of acetic anhydride.*

A mixture of solution  $K_3$  (0.1 ml.) glacial acetic acid (1.0 ml.) and acetic anhydride (1.0 ml.), added in that order, was diluted to 2.5 ml. with glacial acetic acid and left at room temperature for 2 hours. Water (30 ml.) was added, and the solution was concentrated to 1 ml. at 35–40° under reduced pressure, diluted with water and assayed. The total activity was about 2% of that initially present, and this value remained unaltered after the solution had been kept at  $p_H$  10 for half an hour, showing that hydrolysis did not occur in the testing-bath as a result of its alkalinity.

### *Dialysis through cellophane.*

Bags of No. 400 cellophane were soaked before use in repeated changes of silica-distilled water, and silica vessels were used throughout.

The following experiment shows that the active substance and the solid material present in a Kamm solution pass through the dialysing membrane at approximately the same rate. A mixture of solution  $K_3$  (2 ml.) and 0.1% acetic acid (2 ml. together with some toluene) inside the membrane was dialysed at room temperature against 0.1% acetic acid (4 ml. and toluene). The liquid

outside was changed daily, assays were made, and aliquot portions were dried to constant weight at  $110^{\circ}$ . The  $p_H$  remained constant at 3.5.

	Inside sol. at start	Outside sols.					Total
		1 day	2 days	3 days	4 days	7 days	
No. of units	1800	759	579	245	105	63	1751
Weight (mg.)	7.2	2.86*	2.40	1.04	0.46	0.54†	7.30
Units/mg.	250	260	247	236	228	116	—

\* This is a corrected value, solid matter (0.72 mg.) extracted from the cellophane having been present, as shown by a blank determination on a new membrane from the same sample.

† Extraneous solid was seen to be present.

### *Cataphoresis.*

*Cell.* The cell was of plate glass. The dimensions of each compartment were  $4 \times 3 \times 1$  cm.; the dividing membranes consisted of cellophane, No. 400, 0.00126 in. thick, and the electrodes of platinum foil measured  $2.5 \times 2.5$  cm. Each compartment was cooled by coils containing running water, which maintained the temperature in these experiments at about  $18^{\circ}$ . The contents of the centre compartment were stirred mechanically.

*Solutions used.* The preparations used were  $K_2$  (450 units and 24.4 mg. per ml.), a tenfold dilution of  $K_3$  (90 units and 0.36 mg. per ml.), and a solution prepared from  $K_3/10$  by simple dialysis through No. 600 cellophane followed by concentration to 90 units per ml. (called  $K_3 D/10$ ).

*Procedure.* The centre compartment contained the hormone solution (45 units),  $M/10$  buffer solution (1.0 ml.) and water, the total volume being 9.0 ml. The anode and cathode compartments contained water (8 ml.) and 0.1 ml. of the basic and acidic constituents of the buffer solution respectively. The current strength was maintained at 50 milliamps. Measurements of the hydrogen ion concentration of the centre and cathode compartments were made colorimetrically. The reaction of the centre compartment was maintained by the addition of sodium hydroxide or sulphuric acid, and carbon dioxide was passed into the cathode solution when necessary. This reduced the alkalinity to  $p_H$  9.5–10 in the experiments in which the centre compartment was at  $p_H$  1.6–8.5 and maintained it at the same  $p_H$  value as the centre compartment solution in the experiments at  $p_H$  9.5–12.5. It was not possible to maintain these reactions accurately and the values quoted were at times subject to fluctuations of  $\pm 0.4$   $p_H$  unit.

After the experiments had proceeded for 1 hour, the solutions were diluted at  $p_H$  3.5, and were assayed. In the cases of solutions from the centre compartment the contractions were grouped as described by Gulland and Newton [1932], and this procedure was followed whenever possible with the solutions from the cathode compartment. The solutions from the anode compartment never contained more than a trace of activity, too small to be estimated even by single contractions. The results are given in Table V.

In most experiments a few oxytocic units were apparently lost. This discrepancy between experimental and theoretical values may have been due to unavoidable error in the assays, to inactivation by acid or alkali or to electrolytic reduction at the cathode. The loss due to reduction probably became significant in those experiments in which migration to the cathode was extensive.

In an experiment at  $p_H$  3.5–4, similar to those described above but in which 225 units were used, the activity in the centre compartment had fallen to 50%

Table V. *Cataphoresis of oxytomic hormone.*

45 units used in each experiment. Figures show units present at end.

$p_H$	Buffer	$K_2$		$K_3/10$		$K_3 D/10$

after 1 hour and to 4% after 4 hours, showing that all the active material was capable of passing through the membrane under the conditions of these experiments.

*Electrodialysis at acid  $p_H$  values.*

(i) *In 3-compartment cell using norite in cathode compartment.* Two experiments at acid reactions were carried out in the usual apparatus, the alkaline cathode compartment containing norite; in Exp. 1 the reaction of the liquid in the central compartment was maintained at  $p_H$  6-6.5, the least acid reaction at which migration towards the cathode seemed to occur (Fig. 4), whereas in Exp. 2 the reaction was not controlled and fell from  $p_H$  4 to 3.6.

The anode compartment A contained water (9 ml.) and  $N$  acetic acid (0.1 ml.). The centre compartment B contained water (9 ml.) and solution  $K_4$  (1 ml., 1000 units, 189 units per mg.), previously evaporated to dryness to remove acetic acid. The cathode compartment C contained water (9 ml.),  $N$  NaOH (0.1 ml.) and purified norite (100 mg.). The cathode compartment was maintained at  $p_H$  10 by the addition of acetic acid and the temperature was 7-10°. The filtrate from the norite and the anode and centre liquids were adjusted to  $p_H$  3.5; the norite was dried and eluted with 98% acetic acid, the eluate being concentrated and diluted with water for assay. The results, summarised in Table VI, show a fall in the ratio activity/solid weight.

Table VI.

Exp.	Duration of dialysis hours	Current milliamps	Units in				Units per mg. in norite eluate
			Centre	Filtrate from norite	Anode	Norite eluate	
1	2.5	100	625	Nil	Nil	80	178
2	2	44-80	Trace	Nil	Nil	205	105

(ii) *Using additional compartments.* The object of these experiments was to interpose between the cathode and the hormone cations a compartment of which the reaction was maintained at an alkalinity such that the ionisation of the hormone cations of the original acidic solution would be depressed. The molecules would therefore not migrate further to the cathode but would remain in the additional compartment, into which the peptide molecules would not have penetrated.

(a) *A 4-compartment cell* similar to that already described, was constructed with the anode and cathode in the outside compartments. The compartments

were filled as follows: A (anode) and C, *N*/100 sodium acetate (10 ml.); B, solution  $K_4$  (0.5 ml., 500 units) and water (9.5 ml.); D, *N*/100 NaOH (10 ml.). Dialysis proceeded at 50 milliamps for 2 hours, B being maintained at  $p_H$  6-7, C at  $p_H$  9-11. The solutions were assayed as follows: B, 412 units; C, 51 units. Evidently little migration occurred, probably owing to the  $p_H$  value of 6-7 being insufficiently acidic (compare previous experiment immediately above).

(b) *8-compartment cell*. The compartments were filled as follows: A (anode) and B, *N* acetic acid (1 drop) and water (10 ml.); C, solution  $K_2$  (0.5 ml., 225 units) and water (9 ml.); D, F, G, H, I (cathode), *N* ammonia (1 drop) and water (10 ml.). The dialysis was carried out for 20 hours at 5 milliamps. The  $p_H$  values of the compartments were finally: A and B, 2; C, 3.4; D, 4.2; F, 5.0; G, 5.8; H, 11; I, 13. A small amount of solid separated on the membrane of compartment C on the cathodic side; this was collected and dissolved in very dilute acetic acid (solution Y). Assays of the solutions gave the following results:

Solution	A	B	C	D	F	G	H	I	Y
Units	0	0.5	10	1	0	0	7	14	16

(iii) *In 4-compartment cell combined with norite adsorption*. The anode compartment (A) contained *N*/100 acetic acid (10 ml.). Compartment B contained solution  $K_4$  (100 units per ml.; 189 units per mg.) which had been previously evaporated to dryness (8 ml.). Compartment C contained water (8 ml.), norite, and 1 drop of *N* NaOH. Compartment D contained *N*/100 NaOH (10 ml.). During the dialysis the temperature remained at 15° and the  $p_H$  of B fell by about 2 units to 3.6. Compartment C was maintained at  $p_H$  11 by the addition of NaOH. The norite was collected, washed, eluted twice with 98% acetic acid, and the combined eluates were concentrated and diluted with water. The various solutions were assayed (Table VII).

Table VII.

Duration of dialysis hours	Current milliamps	Units at start	Amount of norite mg.	Units contained in				Norite
				A	B	C	D	
1.5	55	1000	100	—	0.6	4.5	3.2	610*
1	100							
2.5	100	275	50	Nil	Trace	Nil	Nil	125
3.0	60	1000	100	Nil	2	6	2	517†

\* 100 units per mg.

† 142 units per mg.; the cellophane membranes used in this experiment had been soaked in water for several days before use.

*Electrodialysis at alkaline  $p_H$  values combined with norite adsorption.*

Solution  $K_4$  (1 ml., 1000 units, 5.30 mg., 189 units per mg.) was evaporated to dryness with water, diluted with water and submitted to electrodialysis in the centre chamber of a 3-compartment cell. The  $p_H$  of the centre compartment was maintained at 11 by means of NaOH, the temperature being 9°. Water was placed in the cathode chamber and also in the anode chamber, through which a continuous slow stream of water was passed to remove any material which entered the chamber. After the dialysis, the active material was adsorbed from the centre solution by norite, leaving no activity in the filtrate, and the norite was washed and eluted twice with 98% acetic acid. The eluates were evaporated to dryness under reduced pressure, and the residue was taken up in water for assay and for weight determination in an aliquot part, dried at 110°.

The amount of solid recovered was variable, and owing to the loss of activity the ratio activity/solid weight fell in each case (Table VIII). Recombination of the solutions from the three compartments did not restore the activity.

Table VIII.

No. of exp.	Duration of dialysis hours	Current milliamps	Weight of norite mg.	Units recovered	Solid recovered mg.	Units mg.
1	3.5	100	150	500	2.85	175
2	1.5	100	120	666	5.30	124
3	4.5	50	200	600	4.66	128
4	3.0	100	250	267	2.40	110

Before being used the cellophane membranes were soaked for several days in repeated changes of silica-distilled water, and in Exps. 2 and 4 the membranes were used in a blank experiment with acetic acid lasting  $2\frac{1}{2}$  hours, in the hope of eliminating water-soluble material. Exp. 4 was carried out at  $4^{\circ}$  and  $p_H$  9.5–10, a cellophane membrane being used on the cathode side of the centre compartment and a membrane of tough filter-paper on the anode side. It was hoped that these modifications would diminish the loss of activity and allow greater ease of passage of the proteose-like material to the anode. The anode and cathode compartments contained 12 and 13 units respectively.

*Electrodialysis of solution containing oxytocic and pressor substances.*

An extract of posterior lobe was concentrated and precipitated by ammonium sulphate and the precipitate extracted with acetic acid, as described by Kamm *et al.* [1928]. This extract (4.5 ml., containing 1080 oxytocic and the same number of pressor units) was evaporated to dryness, dissolved in water and electrodialysed in the centre-compartment of a 3-compartment cell for 3 hours at 50 milliamps and  $10^{\circ}$ . The centre compartment (B) was maintained at  $p_H$  10–11, and the alkalinity of the cathode compartment (C) was reduced to the same value by means of a stream of carbon dioxide. The activities of these solutions and of the anode (A) liquid were assayed as follows. We are greatly indebted to Prof. J. H. Burn for making the pressor assays.

Compartment	...	A	B	C
Oxytocic units		3	610	47
Pressor units		2–2.5	1004	—

SUMMARY.

1. The ultraviolet absorption spectra of posterior lobe extracts and of purified hormone solutions, as at present available, are not characteristic of the hormone molecule but correspond to the substances which accompany it.

2. The nature of the spectra and their comparison with those of proteoses and peptones lead to the conclusion that the substances accompanying the hormone are peptide in character.

3. The effects of the following adsorbents on hormone solutions have been examined—silica gel, aluminium hydroxide Cy, fuller's earth, acid-treated talc, ignited talc, asbestos, purified norite.

4. The purer hormone solutions available were not purified further by these reagents.

5. An outline is given of a technique in which the concentration under diminished pressure and adsorption on a protein-ammonium sulphate precipitate, commonly used in purifying whole, aqueous extracts of posterior lobe, are replaced by adsorptions with fuller's earth and norite.

6. The hormone is inactivated by acetic anhydride.

7. At reactions more alkaline than  $p_H$  8 the hormone remained in the centre compartment of an electrodialysis cell, whereas at reactions more acid than  $p_H$  6 it migrated towards the cathode.

8. Electrodialysis under very varied conditions was not successful in raising the activity/weight ratio of purified hormone solutions, since removal of the proteose-like substances reduced the stability of the hormone towards alkalis.

9. Oxytocic and pressor hormones were not separated by electrodialysis at  $p_H$  10-11.

# CCLXI. AN ABSORPTION APPARATUS FOR THE MICRO-DETERMINATION OF CERTAIN VOLATILE SUBSTANCES.

## III. THE MICRO-DETERMINATION OF CHLORIDE, WITH APPLICATION TO BLOOD, URINE AND TISSUES.

By EDWARD JOSEPH CONWAY.

*From the Department of Physiology and Biochemistry,  
University College, Dublin.*

*(Received July 24th, 1935.)*

### INTRODUCTION.

AN apparatus has been already described for the determination of certain volatile substances [Conway and Byrne, 1933]. It was shown that by its use minute quantities of ammonia or urea [Conway, 1933] could be very accurately and simply determined. The apparatus consists of a small glass dish with thick walls, within which a second chamber is formed by a circular wall of glass arising from the floor of the dish to about half the height of the outer wall. The dish or "unit" with the contained fluids is covered by a glass lid hermetically sealed with some fixative such as vaselin, vaselin *plus* paraffin wax *etc.* After formation in the outer chamber such substances as ammonia, chlorine, carbon dioxide *etc.* can diffuse very rapidly into the central chamber where their tension is reduced to zero on the surface of an absorbing fluid (for details see previous communications. The "units" of standard size are now available from Messrs A. Gallenkamp and Co., Finsbury Square, London).

The principle used in the present micro-determination of chloride consists in oxidising the chloride to chlorine gas by a suitable acid permanganate mixture in the outer chamber, the chlorine so formed being absorbed by potassium iodide in the central chamber, where it liberates an equivalent amount of iodine.

The formation of the chlorine gas takes place quite readily at room temperature and its absorption is complete in one hour and a half.

For a range of chloride down to  $35\gamma$  the liberated iodine is best titrated with sodium thiosulphate solution, most suitably by 0.05N solution from the special burette already described [Conway, 1934]. In this way quantities of chloride of the order 0.3–0.4 mg. chlorine (corresponding to the amount in 0.1 ml. plasma) can be determined with a coefficient of variation of 0.5%.

Over the range  $35\text{--}7\gamma$  chlorine, an accurate determination of the liberated iodine is very conveniently carried out by a direct colorimetric method. This can be done with great facility and without standards by using the "grey solution" of Thiel [1933] (in accordance with the most recent formula as supplied by Leitz, in which grounds for previous objections are removed) and a colorimeter provided with spectral filters. The "grey solution" has a specific extinction coefficient of  $0.500 \pm 0.005$  for nearly the whole of the visible spectrum.

Below  $7\gamma$  chlorine the iodine liberated in the central chamber is determined colorimetrically after adding 0.5 ml. of 0.2% starch. This colorimetric method

with starch may be used for the whole range below 35% chlorine. It is then necessary to use 2 ml. 0.2% starch. An ordinary colorimeter without filters may be used.

(a) *Chloride determination down to 35% chlorine.*

*Method.* Into the central chamber of a "unit" is run approximately 1 ml. of a 20% potassium iodide solution. Into the outer chamber is introduced about 0.2 g. of pure potassium permanganate, taking care that none of the grains are spilled into the central chamber; this may be done without any difficulty when using a spoon spatula. The quantity of permanganate need be only very roughly judged and weighed but once to form an idea of the bulk. 1 ml. of the fluid to be analysed is introduced from an Ostwald pipette into the outer chamber. One of the square glass lids for covering the unit is now lightly smeared all over its surface with the special fixative (see below). The lid is displaced a little to allow the introduction of the tip of a pipette. The unit is slightly tilted—most conveniently by resting the unit on another lid—and 1 ml. of a sulphuric acid solution containing 24–30% by volume of pure sulphuric acid is run into the outer chamber. The lid is immediately fixed in position and the fluid in the outer chamber rotated gently about 10 times to ensure adequate mixing. The unit is then left aside on the bench after being first examined to see if it is sealed all around—which is evident by the transparency of the contact. If necessary a small weight placed on the surface of the lid will ensure this remaining perfectly sealed. After 1½ hours the lid is removed and the contents of the central chamber are titrated with 0.05 *N* thiosulphate from the burette previously described [Conway, 1934], using a drop of starch indicator towards the end. For this titration the Bang 2 ml. standard burette may also be used containing 0.005 *N* thiosulphate.

A blank determination with the reagents is carried out at the same time.

*Calculation of the result.* After subtracting the blank value, the amount of thiosulphate is multiplied by its chlorine equivalent for the determination. This latter may be determined with fresh thiosulphate solution by making an initial duplicate determination of 1 ml. of 0.0141 *N* HCl, each ml. of which contains 0.5 mg. of chloride as chlorine. The burette reading here multiplied by 2 gives the figure required for 1 mg. of chlorine. In the special burette [Conway, 1934] 0.05 *N* thiosulphate is used and when made up with a trace of sodium carbonate keeps for a long period. (See reagents below.)

If the thiosulphate is directly standardised by titration of standard iodine in 20% KI, the result calculated as chloride is multiplied by 1.03. This factor does not arise from the oxidation and absorption of the chlorine not being quantitative but is due to a slight diffusion of the liberated iodine from the central chamber. The factor 1.03 applies for 1½–2½ hours after the addition of the sulphuric acid to the outer chamber. (This point is again referred to in the last section.)

The above method is independent of the presence of protein to the extent of 1 mg., i.e. 0.1% in 1 ml.

If it is found desirable to carry out a determination with greater or lesser volumes than 1 ml., the total acidity in the outer chamber should lie between 12 to 15 volumes % of sulphuric acid. This and other conditions are discussed in the last section (d) of the present communication.

If there is not much organic matter present it may be found more convenient to add the permanganate as 1 ml. of the saturated solution to 1 ml. of the solution for analysis in the outer chamber. The acid subsequently added should be 0.5 ml. of a 60–75% (by volume) of sulphuric acid.

*Notes on the reagents required.*

1. *20% potassium iodide.* This solution does not require to be accurately made up. It should be stored in a brown bottle and is best made in small quantities at a time. A small amount of free iodine will not affect the result since it will be allowed for in the blank. For chloride determinations below 35% chlorine the potassium iodide should however be freshly made up, or at least give no perceptible colour when viewed in a thick layer.

2. *24-30% (by volume) sulphuric acid.* The purest sulphuric acid should be used, 24-30 ml. being run into about 60 ml. distilled water in a beaker and made up to 100 ml. after cooling.

3. *0.05 N thiosulphate.* This is made up in the usual way by dissolving 12.42 g. to make 1 l. of solution. To preserve the solution 50 mg. of sodium carbonate are added per litre.

*Potassium permanganate.* Only the purest material should be used. The crystals are ground to a powder in a clean mortar and preserved for convenience in a small wide-necked stoppered bottle.

*The fixative.* This is formed by melting 50 g. of paraffin wax (M.P. 49°) in 80 ml. of pure liquid paraffin in a beaker and cooling the mixture; more or less of solid paraffin may be used in accordance with the prevailing temperature of the room. The paraffin wax supplied by the B.D.H. is suitable for use, though samples supplied at higher melting points were not sufficiently free from impurities, when carrying out the finest determinations.

*0.2% starch solution.* The most efficient of such solutions found by the author is that of Mutnianski as described by Kolthoff [1931]. In this method 2 g. of soluble starch and 10 mg. mercuric iodide are ground to a paste with a little water and poured into 1 l. of boiling water. The solution is clear and does not alter over a long period if kept in a brown bottle.

*Results of chloride method down to 35% chlorine.* The results given in Table I show that the amount of iodine titrated at the end of the analyses is in strictly linear relationship to the amount of chloride in the outer chamber. The method can deal, practically speaking, with the largest amounts of chloride, but at the same time, as above mentioned, it is advisable for convenience in the titration that the fluid be diluted if necessary so that 1 ml. contains not more than about 0.7 mg. chlorine (or not more than twice the strength of a one in ten blood filtrate). Smaller volumes than 1 ml. may also be used instead of this dilution, with a slightly reduced accuracy. The total acid strength however in the outer chamber should always lie within 12-15% by volume.

Table I.

Amount of chloride analysed (millimols)	Amount of chloride analysed (mg.)	Thiosulphate used, mm. on burette	mm. on burette required per mg. Cl (calc. from columns 2 and 3)
$12.5 \times 10^{-4}$	0.0444	30	675
25 ..	0.0888	60	675
50 ..	0.1775	121	682
100 ..	0.3550	241	679
200 ..	0.7100	481	678
400 ..	1.4200	964	679

The burette readings in column 3 are the average of three determinations. The chloride was contained in one ml. and analysed in accordance with the method described in text.

Table II shows the accuracy to be expected for the individual analysis of quantities of chloride containing about 0.3 mg. chlorine. It gives the first five

Table II.

Amount of chloride analysed mg. Cl	Titration with Bang burette, using 0.005 <i>N</i> thiosulphate		Titration with Conway burette using 0.05 <i>N</i> thiosulphate	
	ml. required	mg. Cl calc. from thiosulphate equi- valent $\times 1.03$	cm. required	mg. Cl calc. from thiosulphate equi- valent $\times 1.03$
0.355	1.935	0.355	23.8	0.354
"	1.950	0.358	24.0	0.357
"	1.930	0.354	23.9	0.356
"	1.955	0.358	23.9	0.356
"	1.970	0.361	24.1	0.358

1 ml. of 0.01 *N* iodine (titrated with 1 ml. 20% KI) required 24.6 cm. with the Conway burette, and 1.995 ml. with the Bang burette.

The above table gives the result of five determinations of chloride in 1 ml. 0.01 *N* HCl, using the Bang burette and five determinations using the Conway burette.

These determinations are the first five in each case of a long series. For 25 determinations using the Conway burette the coefficient of variation found was 0.55%. For 26 determinations using the Bang burette the coefficient found was 0.76 (in this latter calculation one very aberrant result was omitted).

determinations of a series using the Conway burette and of another series using the Bang burette, the amount of chloride used in each determination containing 0.355 mg. chlorine. 23 of the 25 determinations with the first burette gave results within 1.2% of the theoretical, the coefficient of variation being 0.55 for the series. 23 of the 26 determinations using the Bang burette were under 1.3%—the coefficient of variation for the series being 0.76.

(b) *Micro-determination of chloride below 35γ chlorine.*

1. *Without standards.* By the use of more dilute thiosulphate solution the titration method can be carried much lower than 35γ chlorine. Below this level however a colorimetric method will be found more suitable. In this the colour of the formed iodine may be directly examined or firstly treated with starch. By the direct examination accurate determinations may be made to 7γ chlorine. A yellow colour is not a suitable one for colorimetry of the ordinary kind, but by the use of a spectral filter this difficulty is removed. The visual judgment with monochromatic light becomes then a judgment between dark and light and not between depths of colour. While a standard iodine solution may be used on one side, we have found it very convenient to use the "grey solution" of Thiel as already mentioned.

*Method.* In a determination, 1 ml. of 20% potassium iodide is accurately delivered into the central chamber of a specially cleaned unit and into the outer chamber 1 ml. of the fluid for examination. The lid is smeared with the fixative and placed in position. Then in accordance with the usual procedure 1 ml. of an acid-permanganate mixture is introduced into the outer chamber. This acid-permanganate mixture is most suitably formed by mixing equal volumes of saturated permanganate and 60% (by volume) of sulphuric acid in the required quantity. (The mixed solution does not keep and should be used only on the day of mixing.) Two hours after the addition of the acid permanganate mixture, the lid is removed and the iodide in the central chamber pipetted into a micro-colorimeter cup and compared with the "grey solution" of Thiel. If the Leitz colour filters are used, filter No. 3, allowing light of wave-length in the region 464mμ to pass, is suitable to use. The use of this filter is assumed in the calculation.

*Calculation of the result.* The depth of the plunger in the iodide from the central chamber is set at 37.0 mm. and the mm. of "grey solution" on the other

side having a corresponding absorption, gives at once the chloride analysed as  $\gamma$  chlorine, or parts of chlorine per million.

If the light absorption is inconveniently great a simple subdivision of 37.0 is used for the fixed plunger. Thus at about 35 $\gamma$  chlorine the plunger is fixed at 9.25 mm. and at 7 $\gamma$  at 37.0 mm., the result in the former case being multiplied by 4. For the best matching it will be found in general advisable to choose the depth of the fixed plunger so that the equivalent depth of the grey solution for light absorption does not much exceed 10 mm.

*Results of method for 35 to 7 $\gamma$  chlorine.* Table III illustrates the results obtained by the colorimetric method described. For a group of seven determinations of 35.5 $\gamma$  chlorine, the maximum deviation was 1.1 $\gamma$  or 3.1%. For five determinations of 7.1 $\gamma$ , the maximum deviation was 0.5 $\gamma$ , and for 3.55 $\gamma$  with a group of six it was found to be 0.3 $\gamma$ . The table also shows that Beer's law is strictly applicable over the range examined.

Table III.

Chloride added to "unit". $\gamma$ chlorine	Chloride found. $\gamma$ chlorine	No. of analyses	Coefficient of variation	Maximum deviation of individual analyses. $\gamma$ chlorine	Iodine in same quantity as added chloride, contained in 1 ml. of 20% iodide. Values analysed as $\gamma$ chlorine ( $\times 0.97$ )
35.5	36.3	7	1.7	1.1	35.5
7.1	7.0	5	4.3	0.5	7.2
3.55	3.6	2	—	0.3	3.5

For the above determinations the plunger in the iodide pipetted from the central chamber of the unit was set at 37.0 mm. or suitable subdivision, it being advisable not to have the "grey solution" reading much exceeding 10 mm. The "grey solution" depth in mm. with fixed plunger at 37.0 gives at once the  $\gamma$  chlorine analysed, when Leitz filter No. 3 (464  $m\mu$ ) is used.

2. *Chloride determination below 35 $\gamma$  chlorine—using starch.* The addition of 2 ml. of 0.2% starch to the iodine in the central chamber will multiply the light absorption, using the same spectral filter, by 7. The method is described here for chloride quantities at and below 7 $\gamma$  chlorine and with only 0.5 ml. starch addition, in which case the light absorption is multiplied by 14 when compared with the direct colorimetric method. Where the whole region below 35 $\gamma$  chlorine is being investigated by this starch method it is necessary to add 2 ml. of 0.2% starch as already mentioned.

*Method.* The method described in the previous section is followed down to the complete absorption of the chlorine. After the two hours' absorption, 0.5 ml. of 0.2% starch is added to the fluid in the central chamber and mixed, the mixed fluids being then pipetted into a micro-colorimeter cup of 1 ml. capacity. Ordinary colorimetric methods with standards may be used. We have, however, found it somewhat more convenient to work here also with the "grey solution". The advantage is not as great as before, since owing to the variable character of starch solutions a final comparison with a standard cannot be dispensed with. We believe that rather more accurate comparisons may be made with its use and it forms an extra control over the results. Using monochromatic light as before (Leitz filter, No. 3), Beer's law is applicable in the colorimetric analysis with starch down to 1 $\gamma$  or less of chlorine (see Fig. 1).

*Calculation.* The plunger in the starch-iodine from the unit is fixed at 25.8 mm. (or convenient submultiple) and the reading of the "grey solution" with light of wave-length 464  $m\mu$  (Leitz filter No. 3) gives an approximate value for the chloride

analysed as  $\gamma$  chlorine multiplied by 10. A blank determination must be also carried out and subtracted from this figure. Since the starch-iodine colour is very susceptible to change of conditions and varies with the kind of starch used it will be necessary to introduce a correction in the following manner. 0.1 ml. of a 0.02 *N* stock iodine is run into 10 ml. of the 20 % iodide used in the determinations. 5 ml. of the starch solution are then added and mixed. Some of the mixture is pipetted into a micro-cup and the plunger in the mixture set carefully at 3.55 mm. The reading of the grey solution gives the required correction factor

Fig. 1. ——— The chloride found (determined from the liberated iodine  $\times 1.03$ ). ---- The result obtained using the same colorimetric method with the theoretical equivalent of free iodine added immediately to 1 ml. of 20 % potassium iodide. The application of Beer's law is evident. The calculation in text allows for the factor 1.03 and the constant loss of 0.25  $\gamma$  chlorine.

multiplied by 10. The previous result is divided by this factor. To the result now obtained 0.25  $\gamma$  chlorine is added as a constant correction. It has been found with the unit of the present dimensions and using pyrex lids and the fixative already described that there is a constant loss of 0.25  $\gamma$  chlorine. This is clear from Fig. 1. It would appear that chloride in excess of this quantity must be present before free iodine appears in the central chamber.

*Example of calculation.*

	Grey sol. mm. Using filter 3 (Leitz)
Plunger at 25.8 mm. in starch and iodide mixture from a determination	15.8
Plunger at 25.8 mm. in blank	2.9
Plunger at 3.5 mm. in starch and standard iodine mixture	10.4
Calculation $(1.58 - 0.29) \times \frac{1}{1.04} + 0.25 = 1.49 \gamma$ chlorine.	

*Results.* Table IV gives results which are typical of this method. It will be seen that in five analyses of 0.71  $\gamma$  chlorine the maximum deviation was 0.08  $\gamma$  chlorine. The table also gives the values obtained where, instead of the iodine

liberated by the diffused chlorine, standard iodine solutions in 20 % potassium iodide were substituted, of similar strength to the added chloride. In this case the constant addition of 0.25 $\gamma$  chlorine to the calculation was not made, and the figures were divided by 1.03 to correspond to the usual factor.

Table IV.

Chloride added $\gamma$ chlorine	No. of analyses	Chlorine found, $\gamma$ chlorine (including addition of 0.25 $\gamma$ )	Coefficient of variation	Maximum deviation of individual analyses found, $\gamma$ chlorine	Iodine in same quantity as added chloride, contained in 1 ml. of 20 % iodide. Values analysed as $\gamma$ chlorine ( $\times 0.97$ )
7.1	6	7.07	4.6	0.45	7.13
3.55	6	3.57	1.9	0.10	3.58
1.42	11	1.44	5.8	0.13	1.38
0.71	5	0.66	6.6	0.08	0.60
Blanks	8	0.49	9.0	0.11	—

The calculation of the chloride analysed is described in text. It may be noted that for the calculation of the chloride in the blank determinations 0.25 $\gamma$  chlorine has also been added.

*Ultimate blank values.* The blank values following these directions are very low (see notes below on method). In 8 blank determinations the mean value obtained with the plunger at 25.8 mm. in the iodine from the central chamber was 3.1 mm. of grey solution or 2.4 mm. omitting the light absorption by the starch. This quantity amounts to 0.24 plus 0.25 or 0.49 $\gamma$  chlorine, and the maximum deviation from this figure for the eight blanks was 0.11 $\gamma$  chlorine. It will be seen from Table IV that practically all the variation at these lowest regions is due therefore to this variation in the blank value.

*Some notes on the methods for chloride below 35 $\gamma$  chlorine.* To obtain the best results, attention must be paid to the following points:

(1) The units must be specially cleaned. After the ordinary cleaning, as described in a previous communication [Conway and Byrne, 1933], they are treated with a little alcohol and ether and then rinsed a few times with distilled water. They are dried as before, merely by exposure after shaking off the drops, and in a position where they are protected from dust. After drying they may be stored in drawers ready for use.

(2) The use of a suitable fixative is most important and the reader is referred to the note on the fixative at the end of the last section; the lids are best made of pyrex glass.

(3) If the acid-permanganate is free from chloride the blank values by the direct colorimetric method will be practically indistinguishable from zero. It may be freed from chloride by pouring out into a Petri dish to a depth of a few mm. and exposing this to the air for about an hour or two before the determinations. When traces of chloride are present in stock acid and stock permanganate, allowance can also be made after some initial blank determinations.

(4) The acid-permanganate must on no account be blown out, and a simple tube, drawn out somewhat at the end and marked at 1 ml. approximately is the most useful way of introducing the mixture.

(5) The units during the absorption should not be exposed to direct sunlight and are best covered with a light cloth.

(6) With the starch method the starch solution should be centrifuged for five minutes before use. With the plunger at 40 mm. in a mixture of 0.5 ml. of starch and 1 ml. of the 20 % potassium iodide it should require no more than 1 or 2 mm. of the grey solution for equal absorption with the No. 3 filter (Leitz).

(c) *Application to chloride determination in blood, urine and tissues.*

**Chloride in blood.** The chloride is here determined in protein-free filtrates, the most suitable being the tungstate filtrate of Folin and Wu [1919]. Of this filtrate 1 ml. is a suitable volume giving in the subsequent titration a reading of about 250 mm. on the burette scale used [Conway, 1934], the burette containing 0.05 *N* thiosulphate. The method described for quantities down to 35  $\gamma$  chlorine may be followed in detail. It may be found more convenient however to add the acid and permanganate together as 1 ml. of a mixture containing equal parts of sulphuric acid—60 % by volume—and saturated permanganate. This mixture should be freshly made up in the required amount for a group of determinations, the acid and permanganate being kept separate as stock solutions. A blank determination should also be carried out with the reagents in the same dilution.

**Results.** To illustrate the method some determinations were carried out on samples of rabbit blood (whole blood and plasma). A large amount of tungstate filtrate (1 in 10 dilution) was obtained in each case, 1 ml. quantities being taken for the present method and 25 ml. for a micro-method in accordance with the Volhard principle. In these latter determinations 5 ml. of a 0.1 *N* silver nitrate solution were added to 25 ml. of a tungstate filtrate in a 50 ml. volumetric flask, 10 ml. of concentrated nitric acid were subsequently introduced and the mixture was well shaken and allowed to stand for several hours, made up to the mark with distilled water and filtered a few times through chloride-free filter-paper. The excess silver was determined in several 5 ml. portions of the filtrate by titration with standard thiocyanate from a micro-burette with iron alum indicator. Blanks were also carried out. The results of the two methods are given

Table V.

Blood sample	Silver method, % NaCl	"Unit" method, % NaCl
Plasma 1	0.633	0.628
Plasma 2	0.625	0.626
Whole blood 3	0.504	0.511
Whole blood 4	0.504	0.508

Each of the "unit" determinations is the mean of five on the protein-free filtrate. The other results (silver method) are from the means of four determinations of the excess silver in aliquot samples from each protein filtrate to which excess silver was added with subsequent filtration.

in Table V, from which it is clear that they give practically identical results. The variable error in determining the blood chloride by the "unit" method may be taken as the same as that for 1 ml. of 0.01 *N* HCl, namely 0.5 % expressed as a coefficient of variation.

**Chloride in urine.** The chloride in urine may be determined for convenience on 0.1 ml. of undiluted urine (a somewhat higher accuracy will be obtained using 1 ml. of a urine diluted one in ten). The method described for chloride determination above 35  $\gamma$  chlorine is followed. Into the outer chamber is pipetted 0.1 ml. urine from an Ostwald pipette after the addition of approximately 0.2 g. of powdered permanganate, the acid subsequently added to the outer chamber being 2 ml. of 15 % (by volume) sulphuric acid (where 1 ml. of a diluted urine is used 1 ml. of 30 % sulphuric acid should be added). The remaining procedure is the same as before, the titration being carried out two hours after the addition of the acid.

**Results of the method.** Whereas one might have expected the chloride determinations on protein-free filtrates to proceed as with standard solutions, the large amount of organic matter in urine would at first appear likely to introduce

a disturbing factor. Consequently the recovery of chloride added to normal urine and also to strongly albuminous urine was carefully investigated. A sample of normal urine was taken and several determinations of the chloride content made in accordance with the above method. Another series was carried out using 0.1 ml. of the same urine to which was added 1.0 ml. of 0.01 *N* HCl in the outer chamber. A third group of determinations was made with 1.0 ml. *N* HCl. In these latter groups the sulphuric acid added was 1 ml. of 30 % (by volume) to bring the mixture to the required acidity. The results are summarised in Table VI.

Table VI.

Contents of outer chamber apart from oxidising mixture	cm. reading on burette containing 0.05 <i>N</i> thio-sulphate <i>minus</i> blank values	Chloride analysed. Mean value. mg. chlorine
0.1 ml. urine	59.8, 59.8, 60.3	0.859
0.1 ml. urine <i>plus</i> 1.0 ml. 0.01 <i>N</i> HCl	84.8, 84.8, 85.2	1.215
1.0 ml. of 0.01 <i>N</i> HCl	24.8, 24.8	0.355

From the last column 1.215 - 0.859, or 0.356 mg. chlorine has been recovered, 0.355 having been added.

1 cm. on burette = 0.0143 mg. chlorine

Table VII.

Contents of outer chamber in addition to oxidising mixture	Mean burette reading <i>minus</i> blank	No. of determinations	Chloride analysed. mg. chlorine
0.1 ml. albuminous urine	48.7	5	0.697
0.1 ml. albuminous urine <i>plus</i> 1 ml. 0.01 <i>N</i> HCl	73.6	6	1.054
1 ml. 0.01 <i>N</i> HCl	24.8	2	0.355

From the last column the "recovery" of chloride added to urine containing 1.0 % protein is 1.054 - 0.697 or 0.357 mg. chlorine. The chloride added was 0.355 mg.

1 cm. on burette = 0.0143 mg. chlorine.

Blank value = 0.2 cm.

From the last column of Table VI it will appear that 0.356 mg. of chloride—as chlorine—was recovered, 0.355 being added. The recovery is therefore quantitative. Similar results appear for the recovery of chloride added to albuminous urine. The albuminous urine was prepared by the addition of whole blood to normal urine so that the latter contained 4 % blood or approximately 1 % protein. The results of this recovery are given in Table VII.

*The accuracy of the analysis of urinary chloride in 0.1 ml. samples.* The accumulation of a large number of duplicate analyses makes it possible to calculate accurately the coefficient of variation of any single determination, using the requisite formula. The result is 0.7 % and if the mean of duplicates is taken the figure is 0.5 %. (It may be noted that the coefficient for a delivery from a 0.1 ml. Ostwald pipette—without wash out—is 0.3 % approximately.)

*Chloride in tissues.* About 0.200 g. of tissue is accurately weighed on a watch glass and transferred to a small mortar. For convenience of calculation the tissue weighed may lie in the range 0.190–0.210 g. A small quantity of pure quartz sand (Merck) is added to the mortar and from a graduated 2 ml. pipette or micro-burette a volume of distilled water which is calculated as follows. The weight of the tissue is multiplied by 20 and 2.36 subtracted. This with 0.2 g. tissue, for example, will mean the addition of 1.64 ml. (this volume is so chosen that the 2 ml. taken from the subsequent fluid cleared by centrifuging contain the chloride in 100 mg. tissue). The mixture is thoroughly ground to a fine paste, which should require no longer than 2 min. 2.0 ml. of 0.0667 *N*

sulphuric acid are added and 0.2 ml. of 10% tungstate, the mixture being further ground for half a minute. The mixture is transferred to a small centrifuge-tube and centrifuged along with a similar mixture from a blank determination which will contain no tissue but 1.80 ml. distilled water and the remaining reagents as before.

2.0 ml. of the clear fluid are transferred to the outer chamber of a unit containing about 0.2 g. of powdered permanganate and 1 ml. of 20% potassium iodide in the central compartment. The determination is then made in the usual manner, 0.5 ml. of a 60% (by volume) sulphuric acid solution being used. The units are left aside for 2 hours at room temperature and subsequently either titrated or estimated colorimetrically by the method described for chloride in the range 35–7% chlorine.

*Calculation.* Using the above method where 0.2 g. tissue is used, the total fluid volume is 4.0 ml. and the chloride corresponding to 100 mg. of tissue is contained in the 2.0 ml. of the clear fluid after centrifuging. When 0.21 and 0.19 g. of tissue are used in accordance with the above scheme it may be readily calculated that 2 ml. of the clear fluid contain the chloride corresponding to 99.8 and 100.2 mg. of tissue respectively, which for the purposes of the determination are equivalent to 100 mg.

The chloride equivalent of the thiosulphate used in the titration expressed as mg. chlorine gives the g. chlorine per 100 g. tissue.

Where the direct colorimetric method is used, which will be found very convenient, the plunger in the iodide is set at 9.2 mm. and the millimetres of "grey solution", using Leitz filter No. 3, multiplied by 4 gives the mg. chlorine per 100 g. in the tissue.

*Results of method.* In this method the content of the tissue in inorganic chloride is determined, and it is essential to show that no chloride is concentrated on the residual particles to the extent of causing an appreciable error in the determinations. Inorganic chloride diffuses freely and rapidly from tissues as already shown [Conway and Kane, 1934]. With tissues of about 1 mm. thickness it reaches equilibrium in about 15 min. so that for the particles formed in grinding the equilibrium time should be only the fraction of a second. It will be sufficient to show therefore that a measured amount of inorganic chloride added to and ground with the tissue is fully "recoverable". As an illustration of the method and the recovery of added chloride, half a pound of fresh beef muscle was procured. A number of samples each about 0.2 g. were analysed in the manner described above, with the slight difference that exactly 2 ml. distilled water were used in the grinding, the subsequent calculation being therefore somewhat different from the above method. Another group of samples was analysed in a similar manner except that instead of adding 2 ml. distilled water, 2.0 ml. of 0.01 N sodium chloride were added instead, the rest of the procedure being exactly similar. A further group of determinations was made on the solution of 0.01 N sodium chloride used, and also appropriate blank determinations.

From Table VIII it appears that the chloride in the sample of ox muscle was 41 mg. chlorine per 100 g.

According to Table IX after adding chloride solution containing 0.710 mg. chlorine and grinding this with the tissue *etc.* 0.702 mg. chlorine was recovered as the mean of four experiments. This corresponds to a 99% recovery. The recovery of sodium chloride added to beef muscle ground to a fine paste may therefore be regarded as quantitative by this method. Further demonstrations of the validity of the method in the analysis of ionised chloride in tissues would seem unnecessary.

Table VIII.

Wt. of beef sample mg.	Thiosulphate used. Burette reading in mm. <i>minus</i> blank	Total chloride from beef. mg. chlorine	Chloride in 100 g. tissue. mg. chlorine
205	26	0.086	42
205	26	0.086	42
205	25	0.082	40
203	24	0.079	39

Burette factor, 1 cm. = 0.0151 mg. chlorine.

Total fluid volume in mortar = 4.36 ml.

Table IX.

Wt. of beef sample mg.	Thiosulphate used, burette reading <i>minus</i> blank mm.	Total chloride. mg. chlorine	Chloride from beef. mg. Cl	Chloride recovered. mg. chlorine	Chloride added. mg. chlorine
202	236	0.780	0.082	0.698	0.710
201	230	0.762	0.082	0.680	0.710
201	242	0.800	0.082	0.718	0.710
201	240	0.795	0.082	0.713	0.710

Chloride added = 0.710 mg. chlorine and average recovery = 0.702 mg.

(d) *Factors influencing the formation and absorption of chlorine in the above determinations.*

If the conditions are varied from the above descriptions it is essential to know how changes in these conditions will affect the rate of formation and absorption of the chlorine. The factors determining these rates will therefore be very briefly discussed.

(1) *The time-absorption curve at constant temperature.* The process of oxidation by the acid permanganate takes appreciable time so that the curve of absorption depends on two factors, namely the rate at which the chlorine is formed and the rate at which it is absorbed at unit concentration. The curve is nearly linear up to about 60 % of complete absorption as shown in Fig. 2. It may be noted that the absorption of the last few % is very slow compared with the initial rate and is not explicable by the decreased concentration in the outer chamber. It is probably due to the slow release of a little dissolved chlorine from the fixative. Keeping to the conditions of the method described above the absorption of the formed chlorine with its consequent iodine formation corresponds after 90 min. at room temperature to 97.0–97.5 % of the chloride added to the outer chamber.

Within the next hour the absorption increases slowly until all the chloride is absorbed as chlorine but at the same time there has been a slight diffusion of iodine from the central chamber. This iodine diffusion is a constant amount of 1.2 % per hour of the iodine in the central chamber. The net result is that from 1½ to 2½ hours after the addition of the acid to the outer chamber the iodine present in the central chamber corresponds to 97.0–97.5 % of the theoretical equivalent of the chloride in the analytical sample. A factor of 1.03 is therefore required in an absolute calculation of the chloride from the thiosulphate.

(2) *The effect of the permanganate concentration in the outer chamber.* This effect is shown in Fig. 2. The rate of formation and absorption of chlorine from chloride is in practically linear relationship to the permanganate concentration in the outer chamber—at least from about 2 % downwards. The outer chamber in these experiments contained 0.1 ml. of 0.1N HCl, 1 ml. of permanganate

Fig. 2. Curves *D*, *E*, *F* and *G*, represent the chlorine absorptions from the outer chamber containing 0.1 ml. of 0.1 *N* HCl, 1 ml. of 25% (by volume) sulphuric acid and 1 ml. of 5, 2, 1 and 0.5%  $\text{KMnO}_4$  respectively. Curve *C* is similar, solid permanganate being used and 2 ml. of 12.5% (by volume) sulphuric acid. Curve *B* represents the absorption of chlorine from 2.1 ml. of chlorine water in outer chamber. Curve *A* represents the fall in percentage value of free iodine in the outer chamber introduced before a blank determination (allowance being made for blank value). Experiments conducted at room temperature of about 18°.

Fig. 3. Curves *C*, *D*, *E* and *F* represent the absorption rates of chlorine from the outer chamber containing 0.1 ml. of 0.1 *N* HCl, 1 ml. of 5% potassium permanganate and 1 ml. of sulphuric acid of strengths 60, 25, 12.5 and 6.2% (by volume) respectively. Curves *A* and *B* are the same as in Fig. 2.

solution (5, 2, 1 or 0.5%) and 1 ml. of sulphuric acid, 25% by volume (see curves *D*, *E*, *F* and *G* in Fig. 2). With one of the curves (*C*) solid permanganate was used the volume being made up to 2.1 ml. by using 2 ml. of 12.5% (by volume) sulphuric acid. The figure shows also the percentage absorption rate of chlorine (curve *B*) from 2.1 ml. of acidified chlorine water.

Where excess solid permanganate is used (about 0.2 g. added to the outer chamber) the rate of chlorine formation is but little greater than where the concentration of the permanganate in the outer chamber is 2.4%. Water saturated with potassium permanganate at 18° is about 6% (by vol.), but even with the small quantity of fluid in the outer chamber appreciable time may be taken for full saturation.

(3) *The effect of varying the acid concentration in the outer chamber.* Fig. 3 illustrates the effect of changing the acid concentration. The effect on the rate of formation of chlorine is here much greater than that caused by changes in the  $\text{KMnO}_4$ . The figure shows that when the acid concentration reaches 29% by volume of sulphuric acid (see curve *C*) the absorption of the chlorine in the central chamber is very similar to that from chlorine water (curve *B*). At the same time a fall occurs in the total quantity absorbed. Below about 15% sulphuric acid this effect becomes negligible—the theoretical equivalent of iodine to added chloride being present in the inner chamber after two hours (see curve *D*), allowing for the small quantity of iodine diffused during this period from the 20% potassium iodide.

It may be noted that for such chloride determinations as here described, many other "redox" systems with high characteristic potentials were also tried, but the acid permanganate was found the most suitable.

(4) *The effect of the fluid volume in the outer chamber.* It was shown for ammonia determinations by the "unit" method that the percentage absorption rate of a given quantity of ammonia was, other things being equal, inversely proportional to the volume of the fluid in which it was contained. After the addition of alkali to the outer chamber all the ammonia was immediately liberated as gas, its tension being in inverse ratio to the fluid volume. With the chloride determinations however the absorption rate is much faster than the rate of formation with the acid permanganate concentrations used, and the amount of chlorine formed from a given quantity of chloride, under similar conditions, is independent of the volume in which it is contained. Consequently the absorption rate of chlorine is practically independent of the fluid volume in the outer chamber. However, it is found that when the volume exceeds about 3 ml. the last traces of the chlorine are more slowly delivered so that it is advisable to keep the volume below this figure.

(5) *The effect of temperature.* The determinations previously described were conducted at an average room temperature of about 18°. Judging from a few experiments where the temperature was increased to 36° it would appear that there was an increase in the velocity of the whole process of 3 or 4% per degree rise in temperature.

The time for a determination could therefore be halved by conducting the process at 38° instead of at 18°. The fixative described above however cannot be employed for this purpose as it becomes too fluid at such raised temperatures.

On account of the small temperature effect the time for a determination as given above need not be altered if the temperature of the room falls to 14 or 15°.

(6) *Effect of changes in the dimensions of the absorbing apparatus.* The above times and quantities are for the present standard apparatus of the dimensions given in a previous communication [Conway and Byrne, 1933]. If apparatus of

different dimensions is used, and we are dealing with chlorine water, the same principles would hold as considered for ammonia absorption, namely that the absorption rate is proportional to the geometric mean of the surfaces and inversely to the mean distance between. Where, however, the chlorine is formed with comparative slowness as in the above determinations this rate of formation will largely determine the absorption rate, which will be therefore independent to a certain extent of changes in the diffusing distances and surfaces.

#### DISCUSSION.

The chloride is oxidised to chlorine at room temperature in the above methods and the formed chlorine passes by simple diffusion over a few cm. distance. When we consider that it is then converted into its iodine equivalent contained in 1 ml. of 20 % potassium iodide (or smaller volume if required, the dimensions of the apparatus being suitably reduced) we may believe that the practical limit of sensitivity for chloride determinations has been reached for a micro-chemical technique. The minutest quantities of chloride—down to 0.5 $\gamma$  chlorine with the present apparatus—can be very easily and simply determined.

The method has certain important advantages over the Volhard method and its numerous micro-modifications, which may be enumerated as follows.

(1) The end-point is much more satisfactory and the sensitivity of the method far higher for micro-quantities.

(2) The method does not involve the determination of an excess of added reagent such as silver nitrate but the direct determination of the iodine equivalent.

(3) It is independent of the presence of protein when this latter does not exceed about 1 mg. This will mean 1 % of protein when 0.1 ml. is used.

(4) It is independent of the presence of iodide which is oxidised to iodate.

(5) When bromide and iodide are present as well as chloride the iodine determined in the central chamber is the equivalent quantity for the chloride and bromide together. By a slight change in the technique (to be subsequently described) the bromide alone may be accurately determined without the least interference from large quantities of chloride or iodide.

#### SUMMARY.

1. A method is given for micro-determinations of chloride, in which, using the special absorbing apparatus already described [Conway and Byrne, 1933], the chloride is oxidised quantitatively at room temperature to chlorine. This is absorbed in 1 ml. 20 % potassium iodide contained in the central chamber of the apparatus. The iodine liberated in equivalent quantity is titrated with standard thiosulphate (most suitably from the burette already described [Conway, 1934]).

For chloride quantities of about 0.3 mg. chlorine the coefficient of variation for a single determination is 0.5 %

2. Where the chloride analysed is below 35 $\gamma$  chlorine, the liberated iodine is determined colorimetrically. A method has been described in which without using standards accurate determinations are made to 7 $\gamma$  chlorine, at which point the coefficient of variation is 4 to 5 % (1.7 % being found at 35 $\gamma$  chlorine). In this method nothing is added to the iodine, the colour of which is directly investigated.

3. A further extension of micro-determination of chloride—down to 0.7 $\gamma$  chlorine—has been described in which 0.5 ml. of 0.2 % starch is added to the

1 ml. of 20 % potassium iodide in the central chamber at the end of a determination. At these lowest regions (0.7 $\gamma$  chlorine) the coefficient of variation found was 6–7 %, and was due almost entirely to the variation of the blank values. For eight blank determinations of mean value 0.49 $\gamma$  chlorine the maximum deviation was 0.11 $\gamma$  chlorine. For 11 determinations of 1.44 $\gamma$  chlorine the highest deviation was 0.13 $\gamma$ . With 0.7 $\gamma$  chlorine there is no difficulty in making a sharp colorimetric comparison, the light absorption being still quite strong, the fluid from the central chamber having in fact an extinction coefficient of 0.13 for light of wavelength 464  $m\mu$ .

4. The method is independent of the presence of iodide. Bromide if present may be readily removed or separately determined by a slight alteration in the technique, to be subsequently described.

5. The method is independent of the presence of protein when this does not exceed about 1 mg. in the amount analysed.

6. Applications of the method to the micro-determination of chloride in blood, urine and tissues are described. The blood chloride is determined in 1 ml. of a tungstate filtrate (0.1 ml. blood), the coefficient of variation being 0.5 %.

7. The urinary chloride is determined in 0.1 ml. urine or 1 ml. of a diluted urine. The coefficient of variation is 0.7 % for 0.1 ml. urine. The "recovery" of added chloride is quantitative. The method is shown to be independent of protein in the urine up to 1.0 % approximately. This is demonstrated by the quantitative recovery of chloride added to albuminous urine.

8. The tissue chloride is determined in 0.2 g. samples, the "recovery" of chloride added to ground ox muscle being demonstrated as quantitative (99 %).

# CCLXII. THE SYNTHESIS OF RESERVE CARBOHYDRATE BY YEAST.

## II. THE EFFECT OF FLUORIDE.

By RACHEL ANNE McANALLY AND IDA SMEDLEY-MacLEAN.

*From the Biochemical Department, Lister Institute, London, S.W. 1.*

*(Received July 19th, 1935.)*

WHEN studying the incubation of yeast in glucose solutions to which phosphate had been added we found in one series of experiments a low glycogen content which was difficult to reconcile with the results of other experiments apparently carried out under similar conditions. Subsequent investigation revealed that the alkali phosphate used in these particular experiments was contaminated by a considerable amount of fluoride. We were thus led to make a study of the effect on glycogen storage of the addition of sodium fluoride at different concentrations to the glucose and maltose media in which the yeast was incubated both in the presence and absence of added phosphate.

The method of experiment was similar to that already described by us [1935]. In order to be able to compare a larger number of media using the same sample of yeast, the experiments were carried out on a smaller scale, 2 g. of yeast being incubated in 125 ml. of the various solutions to be tested: the only estimations made were those of the glycogen content of the yeast and of the amount of reducing sugar which had disappeared from the medium.

The concentrations of sodium fluoride compared were in most experiments 0.01% (0.0024 *M*), 0.02% (0.0048 *M*) and 0.03% (0.0071 *M*); intermediate and somewhat greater concentrations were also used in a few cases.

### *The effect of the addition of fluoride on glycogen storage.*

When yeast was incubated in a 5% solution of glucose or maltose at 25° the addition of even 0.01% NaF to the medium caused a marked inhibition of glycogen storage; after addition of the fluoride to a 5% solution of glucose or maltose, the glycogen content of a similar sample of yeast incubated in either medium was identical, although without this addition the maltose produced much more glycogen. If however 0.05% phosphate was also added to the medium the effect of the fluoride was considerably modified. The addition of 0.01% NaF to the glucose-phosphate medium did not diminish but markedly increased the amount of glycogen stored: with further increase of the fluoride concentration to 0.03% the glycogen content steadily diminished.

In Fig. 1 the amounts of glycogen stored by 10 g. yeast after incubation in the sugar solution are plotted against the concentration of fluoride. The variability of different samples of yeast obtained on different days from the same brewery has already been pointed out [1935] and it happened that in most of these experiments the glycogen content of the yeast after storage in the glucose-phosphate medium was unusually low and the stimulating effect of the fluoride was marked: in the only sample which after incubation in the glucose-phosphate medium gave a high glycogen value, the increase usually produced by the fluoride was not apparent.

With the samples used for incubation in the maltose-phosphate medium, glycogen storage was particularly efficient, showing a marked increase over the values after incubation in the pure maltose medium: the addition of 0.01 % NaF to the maltose-phosphate medium caused no further increase of glycogen storage but sometimes a diminution. The addition of 0.01 % NaF to the pure maltose medium however always produced a marked diminution of glycogen content; increase above 0.01 % of the fluoride produced a diminished storage both in the presence and absence of phosphates.

Fig. 1. *A*, maltose + 0.10 %  $\text{PO}_4$ ; *B*, maltose + 0.05 %  $\text{PO}_4$ ; *C*, glucose + 0.10 %  $\text{PO}_4$ ; *D*, glucose + 0.05 %  $\text{PO}_4$ ; *E*, glucose; *F*, maltose.

Since the action of the phosphate seemed to a certain extent to inhibit the action of the fluoride, we carried out a series of experiments in which the effect of increased phosphate concentration in the presence of fluoride was observed. The significant rise in glycogen when 0.01 % fluoride was added to the glucose medium containing 0.05 % phosphate was not always apparent when the phosphate concentration was doubled. In the maltose media, increased phosphate concentration, in comparable experiments, showed a diminution of the effect of fluoride in lowering the glycogen content. After incubation in the glucose-phosphate medium, the increase in glycogen storage at a low fluoride concentration (Fig. 1) followed by a decrease at higher fluoride concentrations may be explained on the assumption that two inhibitory processes are at work, one

inhibiting the synthesis, the other the breakdown of glycogen. At low concentrations of fluoride, the breakdown would seem to be most affected whilst at higher concentrations the inhibition of breakdown is counteracted by the inhibition of synthesis.

Further the fact that no such preliminary rise in the glycogen content occurs after incubation in the maltose-phosphate medium at a concentration of 0.01% NaF may be explained by assuming that the inhibition of glycogen synthesis is proportional to the rate of synthesis. The amount synthesised being greater in the maltose than in the glucose medium, the diminution in the amount of glycogen synthesised when fluoride is added will be greater in the maltose solution. Thus if the rates of decomposition of glycogen are the same in both media, it is possible that at a concentration of 0.01% NaF, in the glucose-phosphate solution, the increase due to the inhibition of decomposition is greater than the decrease due to the inhibition of synthesis and a rise in the curve takes place, whilst in the maltose-phosphate solution, the inhibition of synthesis is equal to or greater than the inhibition of breakdown of the glycogen and the curve remains at a constant level or falls.

*The influence of the addition of phosphate and fluoride on the total amount of sugar fermented.*

It is noteworthy that in all experiments in which incubation in the medium has been continued for 48 hours the sugar which has disappeared from the medium when the same sample of yeast has been incubated in glucose and in

glucose-phosphate media respectively has always been greater in the phosphate-containing medium. This is particularly interesting since no such difference seems to have been observed in experiments of shorter duration. Apparently on prolonged incubation phosphate exercises a beneficial effect on the fermentation of glucose by living yeast. With maltose however no such difference was apparent.

Both for maltose and glucose the addition of fluoride to the medium diminished the amount of sugar removed by the yeast cell, but the effect was largely counteracted by the addition of phosphate to the media, 0.1% phosphate being more effective than 0.05%. The results of these experiments are given in Table II.

#### *Variations in the wet weight of the pressed yeast after incubation.*

Table III shows the mean wet weights of 10 g. of the original yeast, filtered on a Büchner funnel under as far as possible similar conditions, after incubation in the various media. The values for individual experiments in any given medium were found to agree surprisingly well; further there appeared to be a correspondence between wet weight and total carbohydrate content of the yeast.

In view of the recent discussion as to whether a constant amount of water is held per g. of glycogen in the liver [Bridge and Bridges, 1932; Puckett and Wiley, 1932; Mackay and Bergman, 1932; 1934] it seemed of interest to compare the wet weights with the amounts of glycogen and total carbohydrate they contained. After incubation in any carbohydrate medium the ratio of the wet

Table III.

	Mean wet wt. of 10 g. original yeast g.	Mean total carbo- hydrate per 10 g. of original yeast g.	Mean glycogen per 10 g. of original yeast g.	Mean wet wt./ Mean total carbo- hydrate	Mean wet wt./ Mean glycogen	No. of experi- ments
Original yeast before incubation	10.0	0.59	0.26	16.9	38.5	8
Incubated in						
5% glucose for 2 days	8.0	0.90	0.35	8.9	22.9	8
5% glucose for 4 days	6.9	0.80	0.38	8.6	18.2	7

5% glucose + PO <sub>4</sub> for 4 days	10.8	1.31	0.81	8.2	13.3	3
5% maltose for 2 days	10.5	1.33	0.73	7.9	14.4	3
5% maltose + PO <sub>4</sub> for 2 days	12.3	1.67	0.83	7.4	14.8	4
5% glucose + PO <sub>4</sub> + 0.035% NaF for 2 days	10.2	1.02	0.24	10.0	42.5	3
5% glucose + PO <sub>4</sub> + 0.035% NaF for 4 days	9.9	1.08	0.30	9.2	33.0	4
5% glucose + PO <sub>4</sub> + 0.035% NaF for 6 days	10.1	1.20	0.24	8.4	42.1	4

weight of yeast to the total carbohydrate is surprisingly constant, but the ratio of wet weight of yeast to glycogen content varies widely. The numbers so obtained for the original yeast (taken directly from the wort) are nearly double those after incubation in the carbohydrate medium. It would appear therefore that the original yeast which had been growing in a nitrogenous medium, when transferred to the non-nitrogenous medium loses some substance other than carbohydrate which holds a considerable amount of water within the cell, but that after incubation for 48 hours in carbohydrate media the wet weight is chiefly dependent on the carbohydrate content of the yeast. As we were not concerned with this question when we planned our experiments we did not always take specimens for the determinations of the dry weights and it has not therefore been possible in a large number of the experiments to calculate the actual water content. Such data as are available show that the differences in dry weight are almost entirely accounted for by the changes in carbohydrate content. According to Daoud and Ling [1931] the insoluble cell carbohydrates consist largely of glycogen esters and Willstätter and Rohdewald [1934] have shown that in the liver part of the glycogen remains bound in the cell in combination with protein. It is possible therefore that the water held would bear a closer relationship to the glycogen content of the cell if any glycogen present in combination in the cell were also contributing to retain water.

#### SUMMARY.

1. Yeast was incubated in glucose, maltose, glucose-phosphate and maltose-phosphate solutions, and sodium fluoride added in concentrations ranging from 0.0024 to 0.0071 *M*.
2. Addition of fluoride to the glucose or maltose solutions always caused marked inhibition of glycogen storage.
3. Addition of 0.0024 *M* fluoride to the glucose-phosphate medium caused a marked increase in the storage of glycogen; with further increase in the concentration of fluoride the glycogen content fell. The effect of the fluoride in diminishing the glycogen storage after incubation in maltose-phosphate solutions was never marked at low concentrations but increased at higher concen-

trations: no actual increase of glycogen such as that shown in the glucose-phosphate medium on the addition of 0.0024 *M* fluoride was observed. An explanation is offered on the assumption that the effect of the fluoride is to inhibit both the synthesis and breakdown of glycogen in the cell.

4. In fermentations lasting 48 hours, addition of phosphate to glucose solutions increased the amount of sugar decomposed but produced no similar effect when added to maltose solutions.

5. Addition of fluoride to the media diminished the amount of sugar which underwent decomposition, the effect being largely counteracted by the addition of phosphate.

6. There appears to be a definite correlation between the wet weight of the yeast and its total carbohydrate content.

# CCLXIII. THE INHIBITORY ACTION OF ESERINE UPON CHOLINE-ESTERASE *IN VIVO.*

BY MAXWELL SHAW JONES<sup>1</sup> AND HENRY TOD.<sup>2</sup>

*From the Royal Edinburgh Hospital for Mental and Nervous Disorders.*

*(Received July 25th, 1935.)*

LOEWI [1921] showed that on stimulation of the vagus supply to the frog's heart a substance, indistinguishable from acetylcholine, could be demonstrated in minute amounts in the fluid filling the heart. More recently Dale [1934] and Dale and Feldberg [1934] have been able to demonstrate that parasympathetic impulses in the peripheral nervous system are transmitted by the liberation of a substance which they have definitely identified as acetylcholine. Further, it has been shown [Feldberg and Gaddum, 1934; Feldberg and Vartiainen, 1935] that stimulation of the pre-ganglionic fibres of the superior cervical ganglion of the cat causes the liberation of acetylcholine in the immediate neighbourhood of the ganglion cell, and this appears to be responsible for the transmission of the impulse to the post-ganglionic fibres.

Feldberg *et al.* [1934] have shown that a stimulus to the splanchnic nerves is chemically transmitted to the effector cells in the suprarenal medulla by the liberation of something indistinguishable from acetylcholine and is, in all probability, the direct stimulant of the medullary cells to secrete adrenaline. Thus the importance of acetylcholine as a humoral transmitter of parasympathetic effects and, in some instances, also of sympathetic impulses has been fully demonstrated. It has been shown by Loewi and Engelhart [1930] that acetylcholine is destroyed in the body by an agent of an enzymic nature. This point has been investigated by Stedman and Stedman [1931] who have called this enzyme choline-esterase and suggested that its action is specific. It has been shown further [Stedman and Stedman, 1932; Loewi and Navratil, 1926; Matthes, 1930] that eserine inhibits *in vitro* the action of choline-esterase upon acetylcholine whereas pilocarpine [Stedman and Stedman, 1931] does not.

In the present paper the choline-esterase is measured by a modification of the method described by Stedman and Stedman at the Glasgow meeting of the Biochemical Society over a year ago, and published by them in another paper in this number of the *Biochemical Journal*. The method is based on that of Krebs and Henseleit [1932], but using the Barcroft differential manometer. It depends on the evolution of CO<sub>2</sub> from physiological salt solution by the acetic acid split off from the acetylcholine used as substrate. The experimental details are as follows:

One ml. of a 1:5 dilution of blood serum is placed in the reaction flask together with 1 ml. of the physiological salt solution and in the control flask 2 ml. of the salt solution. In the side-bulb of each flask is placed 1 ml. of a 2.5 % solution of acetylcholine chloride in distilled water. The apparatus is filled with a gas mixture of 95 % O<sub>2</sub> and 5 % CO<sub>2</sub> composition and is then shaken very gently

<sup>1</sup> Walter Smith Kay Research Fellow, University of Edinburgh.

<sup>2</sup> Biochemist, Royal Edinburgh Hospital.

in a thermostat at 37° until equilibrium is attained (about 10 min.). The taps are then closed and the acetylcholine solution is added to the main flask. The apparatus is shaken at about 120 oscillations per minute and readings of the manometer are taken at 2½ minute intervals. The activity of the serum is then calculated from the formula:

$$\text{C.E.} = \frac{h \times k \times P/760 \times c}{T}$$

In this formula,  $h$  is the difference of levels in mm. for the time interval  $T$  in minutes, on the straight line portion of the curve when  $h$  is plotted against  $T$ ;  $P$  is the barometric pressure;  $c$  the concentration of the serum and  $k$  the constant for the apparatus found by the Münzer and Neumann [1917] method, quoted by Dixon [1934]. The unit thus represents  $\mu\text{l. CO}_2$  per minute per ml. of serum, the volumes being corrected for pressure but not for temperature as they are all estimated at 37°.

With a view to demonstrating this inhibitory action of eserine *in vivo* a group of 12 cases was taken, the conditions standardised as to diet, all drug treatment was discontinued, and all cases were investigated while in bed. 5 ml. of venous blood were removed and a subcutaneous injection of eserine sulphate grs. 1/50 then administered. A further 5 ml. of blood was removed when a definite physiological response to the drug had been obtained. There was in some cases an initial lowering of the blood pressure and slowing of the pulse but this was in most cases followed by a rise of pulse rates and blood pressure, and in 4 cases vomiting occurred. Table I shows the variation in blood pressure and pulse rate from the initial values at the time when the second sample of blood was drawn. The times elapsing between the removal of the 2 specimens of blood varied from 10 to 35 min. The results obtained by using eserine are given in Table I.

As pilocarpine stimulates the parasympathetic, but not by the inhibition of choline-esterase, it appeared to furnish an ideal method of control. The same procedure as described above was adopted on the day following the eserine test, this time using pilocarpine nitrate grs. 1/10. The blood pressure did not vary to any marked extent from the initial reading but there were, in most cases, a definite rise in the pulse rate and salivation, while all cases showed sweating. The control figures are shown in Table II. Further, as the rise of blood pressure found in several of the cases after injecting eserine may have been partly the result of an adrenaline response (Sollmann [1932] states that eserine increases the

adrenaline output in contrast to pilocarpine) it seemed desirable to control the same group of cases with adrenaline. This was done, using m. 7 of a 1 : 1000 solution of adrenaline hydrochloride, and the results obtained are given in Table IV. Two cases were not investigated as, in one case, the patient objected to further interference, while in the other (Case 1) the blood pressure was considered to be dangerously high.

## SUMMARY.

1. It has previously been shown *in vitro* that eserine inhibits the action of choline-esterase on acetylcholine and that pilocarpine, though acting in a somewhat similar manner by producing parasympathetic response, nevertheless does not do so by inhibiting choline-esterase.

2. That these facts obtain *in vivo* has been shown by us.

3. Adrenaline, in an amount sufficient to produce definite alteration in the blood pressure, caused no lowering of the choline-esterase activity.

4. The above facts corroborate the theory that eserine acts on the parasympathetic by virtue of its inhibition of choline-esterase, leading to a prolongation of the action of acetylcholine present.

We wish to acknowledge our indebtedness to Prof. D. K. Henderson for providing us with facilities for carrying out this work, to Messrs E. Merck and Co. of Darmstadt for a generous supply of acetylcholine chloride and to The Medical Research Council for a personal grant to one of us (H. T.).

# CCLXIV. THE EFFECT OF 2:4-DINITROPHENOL UPON CALCIUM, CREATINE AND CREATININE EXCRETION IN THE RAT.<sup>1</sup>

By LEONARD IRVING PUGSLEY.

*From the Department of Biochemistry, McGill University, Montreal.*

*(Received July 15th, 1935.)*

It has been shown by a number of workers that nitrated phenolic compounds have a marked stimulating effect upon metabolism. The literature has recently been extensively reviewed by Dodds [1934] and Tainter and Cutting [1934]. The effect seems in no way to be attributable to thyroid stimulation and in general is decidedly different from the effect of thyroid administration. It has been shown by Pugsley *et al.* [1934] that the administration of desiccated thyroid or thyroxine causes a marked creatinuria and an increased faecal excretion of calcium in rats. This is also true of the thyrotropic hormone of the anterior pituitary [Collip, 1934]. The observed increased excretion of calcium confirms the clinical studies of Aub *et al.* [1929] and Hansman and Wilson [1934] on hyperthyroidism.

In view of these facts it seemed of interest to investigate the effect of 2:4-dinitrophenol upon calcium excretion and simultaneously to study the effect upon creatine and creatinine excretion.

## *Methods.*

The diet, feeding of the animals, and analytical methods were the same as those previously reported by Pugsley *et al.* [1934]. During the experimental period the dry 2:4-dinitrophenol was intimately mixed with the diet. Some difficulty was encountered at first in getting the rats to consume their usual amount of food; however, with the increased metabolic rate which ensued this obstacle was soon overcome. The rats did not appear as ravenous as in the previous work on feeding desiccated thyroid. The creatine and creatinine excretions were followed on the same rats as the calcium studies.

## *Results.*

The effect of feeding 25 mg. of dinitrophenol per rat daily upon the calcium excretion, calcium balance and metabolic rate is shown in Table I. The values represent the average of 8 rats. After a preliminary period of 8 days the dinitrophenol was given for 26 days and then withdrawn and the rats allowed to recover. The faecal calcium was increased to approximately twice its control level within 10 days and remained at this high level during the feeding of the drug. The calcium excretion in the urine was not significantly altered, except on withdrawal of the dinitrophenol when a slight increase occurred. The calcium balance is shifted from a positive value of 1 mg. daily during the control period

<sup>1</sup> A preliminary account of this work was reported at the meeting of the Royal Society of Canada, May 1935.

Table I. *The effect of dinitrophenol upon the calcium excretion of adult rats (8 animals).*

	32	0.02	5.50	-3.24	—
	34	0.01	5.75	-3.72	—
Dinitrophenol discontinued	36	0.03	4.45	-1.72	—
	38	0.35	2.76	+0.49	—
	40	0.40	2.62	+0.58	—
	42	0.40	2.62	+0.58	—

to a negative value of 2-3 mg. daily during the experimental period. On withdrawal of the dinitrophenol the calcium balance becomes positive and a decided decrease in the faecal calcium is observed. The metabolic rates were determined every week and are expressed as the percentage increase in oxygen consumption over that found in the control period. The variations are probably due to the fact that the rats had not consumed as much of the dinitrophenol before the test as they had in some of the other determinations. Magne *et al.* [1932] report a rapid habituation to the drug in large non-lethal doses and such may have occurred here. The metabolic rates were determined at approximately the same hour on each occasion.

Table II. *The effect of dinitrophenol upon the creatine and creatinine excretion of adult rats (8 animals).*

Treatment	Days	Creatinine mg./100 g. body wt. daily	Creatine mg./100 g. body wt. daily	Body wt. g.
—	2	2.62	0.60	266
	4	2.65	0.63	262
	6	2.57	0.53	266
	8	2.66	0.62	266
25 mg. dinitrophenol daily from 8th to 32nd day	10	3.84	2.84	261
	12	3.96	3.16	253
	14	3.84	3.18	249
	16	3.84	3.10	239
	18	3.74	4.10	230
	20	3.88	3.30	225
	22	3.20	3.36	223
	24	3.22	3.68	218
	26	3.46	3.96	210
	28	3.43	4.47	201
	30	3.46	4.75	197
	32	3.28	5.25	187

*Note.* The creatine is expressed as creatinine.

In a preliminary study in this investigation the dinitrophenol was given by subcutaneous and intraperitoneal injections of the sodium salt; here the results were not very satisfactory, owing to the short duration of the effect on the metabolic rate and the rapid excretion of the dinitrophenol. No definite rise in the calcium excretion was elicited by this technique even when the dose was divided and administered 3 times daily. Intraperitoneal injections of dinitrophenol dissolved in olive oil were also not very satisfactory in producing a definite increase in calcium excretion.

The results of feeding 25 mg. of dinitrophenol per rat daily on the body weight, creatinine and creatine excretion are shown in Table II. These results are in agreement with those previously reported for drugs which produce a loss of body weight, a decrease in glycogen stores and an increased excretion of creatine and creatinine. The creatinine excretion is increased to approximately 45% above the control level and the creatine excretion is 4 times as great as during the control period. The loss of body weight is approximately 3 g. daily. A creatinuria of about the same extent was produced by intraperitoneal injections of the sodium salt in a dosage of 5 mg. 3 times daily.

#### DISCUSSION.

It appears from these results that substances which produce a prolonged elevation of the metabolic rate are capable of causing an increased excretion of calcium in the faeces. In cases where a transient increase in metabolic rate occurs, as with intraperitoneal injections of dinitrophenol, the effect is not so clearly shown. This increased excretion of calcium in the faeces would probably not occur with therapeutic amounts of dinitrophenol, since the dosage used in these experiments is proportionately very much larger than that usually prescribed for human beings. Although Aub *et al.* [1929] were unable to find any increase above the normal level in clinical cases with increased metabolic rate due not to hyperthyroidism but to subacute infections, it appears from these results that a time factor is involved in producing the effect.

Rabinowitch and Fowler [1934] reported an increased blood creatinine in patients receiving dinitrophenol. Most workers agree that the urinary nitrogen is unchanged or slightly increased with toxic doses of the drug [Magne *et al.*, 1932; Tainter and Cutting, 1934; Furth and Rapport, 1934]. The increased creatine and creatinine excretion found in these experiments would probably not be considered significant when calculated as total nitrogen.

#### SUMMARY.

The feeding of 25 mg. of 2:4-dinitrophenol per rat daily caused an increased excretion of calcium in the faeces similar to that produced by feeding desiccated thyroid. A marked creatinuria and an increased excretion of creatinine was also observed.

I wish to express my indebtedness to Prof. J. B. Collip and Dr D. L. Thomson for advice during the course of this work. I am also indebted to Dr E. M. Anderson for assistance in determining the metabolic rates.

*Note added September 15th, 1935.* After this paper had gone to press a paper by Lieben and Asriel [1935] came to the author's notice reporting an increased excretion of creatine in rabbits after the subcutaneous injection of dinitrophenol. Also Robbins [1935] recently reported that the administration of dinitrophenol to patients had no effect on their calcium and phosphorus excretion.

# CCLXV. THE DETERMINATION OF ASCORBIC ACID IN URINE WITH PHOSPHO-18-TUNGSTIC ACID.

By GRACE MEDES.

*From the Lankenau Hospital Research Institute, Philadelphia, Pennsylvania.*

*(Received July 22nd, 1935.)*

THE use of 2:6-dichlorophenolindophenol as an indicator in the quantitative estimation of ascorbic acid is open to the objection that the reaction is non-specific in that phenols and thiol compounds (especially cysteine) reduce the reagent. Birch [1933] has shown that in acid solutions glutathione does not interfere. At  $p_H$  3 the action of phenols is suppressed or delayed [Johnson and Zilva, 1934] though cysteine reacts. Emmerie and van Eekelen [1934] removed cysteine by precipitation with mercuric acetate. The method, as worked out by them, whilst yielding more highly accurate results requires several hours (overnight) for completion. In all cases the end-point of the reaction is far from clear and varies somewhat with the speed of titration.

The reduction of phospho-18-tungstic acid by ascorbic acid is the basis of the method proposed here. It offers the advantages of simplicity, speed and accuracy. By carrying out the reaction in acid solution none of the other reducing substances of urine except thiol compounds interfere [Lugg, 1934]. Since the action of thiol compounds can be prevented by addition of formaldehyde [Mason, 1930] or of mercuric salts [Shinohara, 1935] the reaction becomes highly specific for ascorbic acid.

## *Method.*

*Reagents.* *M* formaldehyde.

*Sodium acetate-acetic acid buffer* at  $p_H$  5 [Shinohara, 1935] made in the proportion of 100 ml. of 2 *M* sodium acetate to 30 ml. of 2 *M* acetic acid.

*Folin's uric acid reagent* [Folin, 1934].

*Ascorbic acid standard*, 0.001 *M*. This solution is unstable and oxidation sets in immediately. It may be preserved for a number of days if saturated with  $H_2S$  and kept in an ice-box.  $H_2S$  must be blown out with nitrogen or carbon dioxide before using. The colour standards are stable for a period of several days if kept in the cold and dark.

*Procedure.* To 5 (1-5) ml. of urine in a 25 ml. volumetric flask add 1 ml. of formaldehyde solution. Into three other 25 ml. volumetric flasks pipette 1, 2 and 4 ml. of the ascorbic acid standard respectively. To each flask add 6.5 ml. of the buffer solution followed by 1 ml. of the uric acid reagent. Adjust the volume and read in the colorimeter after 20 min.

*Calculation.*  $0.001 \times \frac{N}{n} \times \frac{20}{R} \times 0.1 = g.$  mols. ascorbic acid per 100 ml. of urine, where *N* represents ml. of standard, *n* represents ml. of urine and *R* reading of colorimeter with standard set at 20.

## *Results.*

*Rate of colour development.* The blue colour produced by ascorbic acid with phospho-18-tungstic acid reaches full intensity in about 3 min. at room temperatures ( $26^\circ \pm 4^\circ$ ). Addition of formaldehyde inhibits the rate of colour development though it does not prevent full intensity from being attained. Fig. 1

shows the effect of addition of 1 ml. of 1, 5, 10 and 37 % formaldehyde respectively. In all cases the reaction was completed within 20 min. When ascorbic acid is added to urine in the presence of 1 ml. of *M* formaldehyde in a final volume of 25 ml., the time required for the colour to reach a constant level varies with the sample of urine from 8 to 15 min.

Fig. 1. Increase in colour intensity *I* with time (min.) of solutions of ascorbic acid in the presence of varying amounts of formaldehyde. 1 ml. of 0.001 *M* ascorbic acid, 6.5 ml. of sodium acetate buffer, 1 ml. of phospho-18-tungstic acid reagent and 1 ml. of formaldehyde of varying concentrations in 25 ml. of solution. *A*, no formaldehyde; *B*, 1 % formaldehyde; *C*, 5 %; *D* 10 %; and *E*, 37 %.

Table I. *Proportionality between colour intensity and concentration of ascorbic acid in pure solutions and in urine. The determinations were made in each case in a total volume of 25 ml.*

Standard ascorbic acid 0.001 <i>M</i> ml.	Test sol. ascorbic acid 0.001 <i>M</i> ml.	Urine ml.	<i>R</i> Standard	<i>R</i> Test sol.	Found test sol. <i>M</i>	Recovered %
1	0.5	—	20	39.5	—	99
	1	—	20	20.0	—	100
	2	—	20	10.0	—	100
	4	—	20	5.0	—	100
	6	—	20	3.3	—	100
	8	—	20	2.6	—	96
					(per 100 ml.)	
4	—	2	10	29.0	4.14	—
	—	5	20	23.3	4.12	—
	—	10	20	11.7	4.10	—
					(per sample)	
4	—	5	20	15.8	2.53	—
	2	5	20	8.9	4.49	98
	4	5	20	6.1	6.55	100
	6	5	20	4.7	8.51	100

*Ascorbic acid concentration and colour intensity.* A series of standards is recommended in the procedure given above although the proportionality between concentration and colour holds over such a wide range that fewer standards may be employed as shown in Table I. In the first group of data it may be seen that in pure solutions of ascorbic acid the unknown may contain as much as six times the standard solution and yet be determined accurately. In the second group the ascorbic acid in 2, 5 and 10 ml. samples of urine was determined with an error of 0.5% using a single standard colour mixture. In the third group, 2, 4 and 6 ml. of 0.001*M* ascorbic acid added to 5 ml. of urine were determined with one standard solution within an error of 2%.

*Relative colour intensities produced by ascorbic acid and cysteine.* A comparison of colour produced by ascorbic acid with those produced by cystine reduced by tin powder in HCl and by cysteine standardised by the method of Shinohara [1935] indicates that cystine and ascorbic acid in equimolar concentrations produce the same colour intensity (*M* ascorbic acid = 2*M* cysteine). This interchangeability of standards in cysteine and ascorbic acid determinations may prove convenient, especially in determinations of the former, since pure ascorbic acid is more readily obtainable than is pure cysteine.

*Stability of colour standards.* If the colour mixtures are kept in the cold, the intensity remains constant over a period of several days. Six tests on mixtures made up 5 days previously and kept in a refrigerator at 0–2° showed 100% colour intensity.

*Oxidation of ascorbic acid.* Ascorbic acid in urine oxidises rapidly, the rate depending upon temperature, intensity of light and  $p_H$ . Johnson and Zilva [1934] state that when urine is immediately acidified with sulphuric acid the ascorbic acid remains stable for several days. Emmerie and van Eekelen [1934] reduced the reversibly oxidised compound with  $H_2S$ . If freshly voided urine is acidified with acetic acid and saturated with  $H_2S$  the ascorbic acid remains unchanged for at least 24 hours.

*Procedure.* Pipette 5 (1–5) ml. of urine into a test-tube, add 1.5 ml. of 2*M* acetic acid and saturate with  $H_2S$ , washing off the tip of the  $H_2S$  tube with a few drops of water. When ready to complete the determination bubble carbon dioxide or nitrogen through the solution for 20–30 min. Wash the tip of the generator tube, add 5 ml. of 2*M* sodium acetate, 1 ml. of *M* H.CHO solution and 1 ml. of the uric acid reagent. Adjust the volume and read in the colorimeter after 20 min.

Fig. 2 depicts three curves (*A*, *B* and *C*) representing the rate of oxidation of ascorbic acid in three samples of the same urine adjusted to  $p_H$  5.0, 6.5 and 8.0 respectively and kept in the light at  $27^\circ \pm 3^\circ$ . After various intervals of time portions were removed, treated as above and kept with the  $H_2S$  for 12 hours. The broken lines indicate the subsequent increases in their reducing ability.

As may be seen, rates of oxidation were approximately the same at  $p_H$  5.0 and 6.5. At  $p_H$  8.0 oxidation occurred rapidly, about 40% having been lost after 4 hours. At this time the reaction was completely reversible as shown by the broken line. After 8 hours, 66% of the ascorbic acid was oxidised in the alkaline medium, about 10% subsequently failing to become reduced with  $H_2S$ . After 12 hours only 18% remained unoxidised. At this time very little reversibility of the reaction was shown. At the end of 24 hours no unoxidised ascorbic acid could be detected in the alkaline medium and no reversibility of the reaction could be demonstrated. On the other hand, the ascorbic acid in the acid solutions had lost only about 40% of its reducing ability and regained the latter completely after treatment with  $H_2S$ .

*Comparison of results with the phospho-18-tungstic acid and dichlorophenol-indophenol methods.* Series of determinations made by these two methods agreed within  $\pm 8\%$ . Repeated determinations on the same sample of urine

Fig. 2. Rate of oxidation of ascorbic acid in urine at various  $p_H$ . Abscissa represents time in hours and ordinate,  $I$ , intensity of colour developed. The broken lines indicate degree of reduction of the oxidised ascorbic acid after different stages of oxidation. 5 ml. of urine, 6.5 ml. of acetic acid-acetate buffer, 1 ml. of  $M$  formaldehyde and 1 ml. of uric acid reagent per 25 ml. of mixture.

by the method proposed here showed variations of less than 2%, whereas in our hands the variations with the indicator method showed much wider discrepancies between repeated determinations on a single sample.

*Inhibition of colour production by cysteine by means of mercuric chloride.* Mercuric chloride added to a solution of cysteine completely inhibits the action of the latter upon phospho-18-tungstic acid. Mercuric chloride also prevents the development of colour by ascorbic acid unless sulphite is present in the reaction mixture. Cysteine in the presence of mercuric chloride and sulphite gives no colour with the uric acid reagent.

*Procedure.* To 5 (1–5) ml. of urine in a 25 ml. volumetric flask, add 1.5 ml. of  $M$   $\text{NaHSO}_3$ , followed by 6.5 ml. of sodium acetate buffer, 2 ml. of 0.1  $\text{HgCl}_2$  and 1 ml. of the uric acid reagent. Adjust the volume and read after 20 min.

In this procedure it is important that the bisulphite be added before the mercury salt since otherwise the latter partially oxidises the ascorbic acid and bisulphite fails to reduce it again. The degree of oxidation depends upon the time interval between the addition of these two components of the reaction mixture, and may be only 5% if the bisulphite is added immediately after the mercury salt.

Sodium sulphite may be substituted for the sodium bisulphite with observation of the same precaution as to order of addition of the various constituents of the mixture. Sodium sulphite produces an appreciable colour with the uric acid reagent and theoretically a blank should be subtracted. However, the error in determining the blank is so great that deducting it fails to reduce the error.

Table II gives a series of comparative determinations by the (a) formaldehyde, (b) mercuric chloride and bisulphite, (c) mercuric chloride and sulphite, and (d) indicator methods. As may be seen, the results by the two first methods are in almost perfect agreement. The other two methods show wider variation.

Table II. *Ascorbic acid excreted during 3-hour periods by one individual on diets of varying ascorbic acid content, as determined by the formaldehyde, mercuric chloride and bisulphite, mercuric chloride and sulphite and indicator methods.*

$M \cdot 10^{-4}$			
H.CH(O)	HgCl <sub>2</sub> and bisulphite	HgCl <sub>2</sub> and sulphite	Titration
2.00	2.00	1.94	2.15
3.20	3.20	3.25	3.40
7.61	7.57	7.58	7.34
1.07	1.07	0.99	1.29
5.32	5.32	5.37	5.63

*Reduction of oxidised ascorbic acid.* The only one of the reducing agents employed here which is able to reduce the reversibly oxidised compound is H<sub>2</sub>S. Sulphite, even after 12 hours, reduces it only slightly. Tin dust and HCl also produce only slight reduction. In one instance a 0.002 *M* solution of ascorbic acid, on standing in the laboratory for 5 hours had lost 30% of its reducing ability. It could not be reduced with tin powder or sulphite, but after treatment overnight with H<sub>2</sub>S all of its original reducing power was recovered.

#### SUMMARY.

A method is described for the determination of ascorbic acid in urine by use of Folin's phospho-18-tungstic acid reagent.

Phenols and thiol compounds do not interfere with the test.

A simple method is described for the preservation of urine for several hours. It may also be employed for reduction of the reversibly oxidised ascorbic acid.

An alternative method is offered with mercuric chloride and sodium bisulphite. With sodium sulphite the error is greater.

The findings by the formaldehyde method agree within about  $\pm 8\%$  with those obtained by the dichlorophenolindophenol method.

# CCLXVI. THE SYNTHESIS OF AMINO-ACIDS.

## III. TRYPTOPHAN.

BY WILLIAM JOHN BOYD AND WILLIAM ROBSON.

*From the Department of Physiology, University of London, King's College.*

*(Received July 25th, 1935.)*

TRYPTOPHAN was first synthesised by Ellinger and Flamand [1907] by the classical Erlenmeyer method. The yield of the amino-acid was however only 15–20% of the theoretical amount obtainable from the indole-3-aldehyde employed. Using the identical procedure, Ellinger and Matsuoka [1914] and Barger and Ewins [1917] prepared 2-methyltryptophan from 2-methylindole-3-aldehyde. In both these cases, as in that of tryptophan itself, the final product had to be purified by precipitation with mercuric sulphate. Barger and Ewins obtained over 40% of the theoretical amount calculated on the aldehyde.

Majima and Kotake [1922], on the other hand, synthesised tryptophan by condensing indole-3-aldehyde with hydantoin by heating these substances together in the presence of acetic anhydride and sodium acetate, reducing the product with sodium amalgam and hydrolysing the saturated hydantoin with strong aqueous barium hydroxide. These workers also used the mercuric sulphate precipitation for the isolation of the amino-acid. Robson [1924] prepared 5-methyltryptophan by a method similar to that of Majima and Kotake, but omitted the mercuric sulphate precipitation. The yield however was very low. This synthesis has recently been repeated by Gordon and Jackson [1935] but no better results are reported.

On attempting in this laboratory to repeat the results obtained by Ellinger and Flamand, great difficulty has invariably been experienced at the reduction stage of the synthesis both of tryptophan and of its homologues. The product of the reaction was always an amorphous precipitate which resisted all attempts at crystallisation. Moreover, hydrolysis of the product failed to yield appreciable amounts of the amino-acid, although the final solutions gave the typical colour reactions of tryptophan in moderate degree. Similar trouble was experienced with Majima and Kotake's method more particularly when applied to the synthesis of 5-methyltryptophan [Robson, 1924].

In looking for a possible explanation of the difficulty, it appeared highly probable, since indole is itself so easily hydrogenated by much the same means as has been used for the reduction of these benzamidoacrylic acids, that there was present in the reduction product not only benzoyltryptophan together with some unchanged  $\alpha$ -benzamido- $\beta$ -indolylacrylic acid but also the corresponding dihydroindole compound. Such a mixture might be expected to be difficult to crystallise.

Such reasoning led to the quest for another mode of reducing the double bond of the side-chain without affecting the nucleus. It has been shown by the authors [1935, 2] that in the reduction stage of the hydantoin synthesis of aromatic amino-acids, sodium amalgam can be satisfactorily replaced by ammonium sulphide, and that excellent yields of phenylalanine, methoxyphenylalanine and tyrosine can be obtained in this way.

On applying this modification to the synthesis of tryptophan an unforeseen difficulty appeared in the insolubility of indolalhydantoin in the various solvents used so successfully for the preparation of benzylhydantoin and phenylalanine. The rate of reduction of indolalhydantoin is slower than that of benzalhydantoin even in aqueous ammonium sulphide and scarcely proceeds at all at 100° in non-aqueous hydrogen sulphide solutions even when the indolalhydantoin is all in solution. This accentuates the difficulty arising from the insolubility.

Moreover, owing to the insolubility of indolylhydantoin it is difficult to free it from the last traces of indolalhydantoin. For these reasons the attempt to prepare indolylhydantoin directly in good yield and purity has not been successful. The search for a suitable solvent has greatly delayed the publication of this work. These difficulties have been surmounted, however, by combining the reduction and the hydrolysis in one operation involving heating of the indolalhydantoin with ammonium sulphide-ammonium hydroxide solution for 500 hours at 100–105°, whereby a 50–60 % theoretical yield of colourless, analytically pure tryptophan is obtained from such small quantities as 2–3 g. of indolalhydantoin without the necessity of a mercuric sulphate precipitation or even of a recrystallisation. A second crop of slightly less pure amino-acid brings the yield up to 70 % of the amount theoretically obtainable from the indolalhydantoin. By carrying out the reaction at a higher temperature, the time can be considerably shortened but the practical difficulties attendant on such a procedure render the lower temperature preferable.

It may be added that the solubility difficulty is not so great in the preparation of 7-methyltryptophan which will be described in a later paper.

Finally, the piperidine method of preparing indolalhydantoin has considerable advantages over the acetic anhydride-sodium acetate method as shown by the better yield and purity of the product obtained (*cf.* Boyd and Robson [1935, 1]).

#### EXPERIMENTAL.

*Indole-3-aldehyde.* The preparation of this substance with improved yields has already been described [Boyd and Robson, 1935, 3].

*Indolalhydantoin.* Indole-3-aldehyde (6.5 g.), hydantoin (5.4 g. or 1.2 mols.) and piperidine (20 ml.) were heated together under a reflux condenser for 30 min. After 15–20 min. the highly coloured solution began to deposit a yellow crystalline precipitate of indolalhydantoin piperidine salt. The mixture was poured into a large bulk of water and acidified with acetic acid. The precipitate was collected, washed with methyl alcohol to remove any unchanged aldehyde and some colouring matter and finally recrystallised from glacial acetic acid. Yield 6.6 g. or 65 % of the theoretical. It melted at 330° (Majima and Kotake found 325°) and contained 18.29 % N.  $C_{12}H_{10}O_2N_2$  requires 18.50 % N.

*Tryptophan.* Indolalhydantoin (2.5 g.), 16 % ammonium sulphide (50 ml.) and 3 % ammonium hydroxide (20 ml.) were heated in a closed vessel at 100–103° for 500 hours. At the end of that time 0.24 g. of unchanged indolalhydantoin (M.P. 327°) was filtered off. The filtrate was evaporated to dryness *in vacuo* and the residue extracted repeatedly by boiling it with fresh quantities of water containing a little ammonia, the total volume amounting to about 700 ml. The insoluble residue was treated with a little carbon disulphide to remove sulphur and the mixture filtered. The insoluble residue was again boiled out with ammoniacal water and the suspension filtered. The filtrate was added to the previous extract. The combined ammoniacal extracts were concentrated to 400 ml., boiled with a little animal charcoal, filtered and concentrated to 100 ml.

Alcohol (400 ml.) was added to the concentrate and the solution set aside. The amino-acid which crystallised out slowly was filtered off, washed with 80% alcohol and dried. It weighed 0.98 g., melted at 275–282°, and contained 13.76% N (micro-Kjeldahl).  $C_{11}H_{12}O_2N_2$  requires 13.72% N.

A further crop of 0.45 g. of slightly less pure product was obtained by concentrating the mother liquor to 10–20 ml. and adding 100 ml. of alcohol. The total amount of tryptophan isolated was 70% of the theoretical figure, but further amounts of very impure amino-acid were obtained together with a little impure indolylhydantoin.

The 3:5-dinitrobenzoyl derivative melted at 240°, after preliminary softening at about 230°. The 3:5-dinitrobenzoyl derivative prepared from a sample of *l*-tryptophan isolated from caseinogen softened and melted at the same temperatures as the derivative of the synthetic amino-acid. A mixed melting-point likewise gave 240° (Saunders [1934] gives 233°).

A second experiment was carried out wherein indolalhydantoin (2.3 g.) was heated in a sealed tube with ammonium sulphide (8 ml.) and alcohol (4 ml.) for 5 hours at a temperature ranging from 150 to 175°. The product was worked up as described above, the amino-acid being finally crystallised from 60% alcohol. The total yield was only 0.4 g., and it melted at 275–287°.

#### SUMMARY.

By using piperidine as catalyst for the condensation of indole-3-aldehyde with hydantoin and ammonium sulphide as the reducing and hydrolytic reagent, tryptophan can be prepared without difficulty in good yield and purity. The method, which does not involve the usual precipitation with mercuric sulphate, is readily applicable to the preparation of small quantities of the amino-acid.

# CCLXVII. THE HEMICELLULOSES.

## II. THE ASSOCIATION OF HEMICELLULOSES WITH LIGNIN.

By ARTHUR GEOFFREY NORMAN  
AND (IN PART) JAGESHWAR GOPAL SHRIKHANDE.

*From the Biochemistry Section and Fermentation Department,  
Rothamsted Experimental Station.*

*(Received July 30th, 1935.)*

THE encrusting hemicelluloses have been presumed by most workers to exist in the cell-wall in a free condition, that is to say, not in chemical union with any other constituent. Preece [1931], in his work on boxwood, made a distinction between "free" and "combined" hemicelluloses, the former being soluble in cold 4% NaOH and the latter only going into solution on heating. He stated, however, that these terms were not to be understood literally but implied only a difference in case of extraction. Recently, Harris *et al.* [1934] have made a detailed study of the lignin from sugar maple wood and of the methylation of maple lignin *in situ* in the wood. They were unable to increase the natural methoxyl content of the lignin unless a preliminary acid hydrolysis were given. They concluded that the active "hydroxyls of lignin were not free for methylation until after hydrolysis, and that the lignin must, therefore, be attached to some of the carbohydrates, possibly the hemicellulose, in the wood cell". Further, they believed that such a combination between lignin and carbohydrate would have the effect of stabilising the lignin naturally in the enolic form, as opposed to the keto-condition in which isolated lignin is obtained. Harris *et al.* [1934] found support for this view in the observation that maple lignin *in situ* took up more chlorine than when freed by isolation. In the naturally occurring enolic form the lignin would be unsaturated and therefore more reactive. While these observations cannot be taken as proving beyond doubt the linkage of lignin with the encrusting hemicelluloses or polyuronides in the cell wall, they are sufficient to show that such a union is possible. In this paper is described some evidence, obtained by entirely different means, which points to the same conclusion.

A study has been made of the removal of lignin and encrusting hemicelluloses from various materials by means of sulphite with and without previous chlorination. Alternate exposure to chlorine and extraction with boiling sodium sulphite form the basis of the well known Cross and Bevan method for the isolation of cellulose. This procedure seems to have been devised solely with a view to the removal of lignin by reason of the formation of "lignone chloride", and its solution in hot sulphite. The concurrent removal of encrusting hemicelluloses appears to be incidental and has not been hitherto investigated. Norman and Jenkins [1933] gave the results of a few experiments on oat straw which showed that chlorination is apparently as necessary for the removal of the encrusting polyuronides as for that of lignin. Three treatments with hot sulphite solution alone effected the extraction of 57% of the lignin and a reduction of but 15% in the total furfuraldehyde yield. When, however, gaseous chlorination treatments were given alternately with three sulphite extractions, 83% of the lignin

was removed, and the furfuraldehyde yield was reduced by 40 %. Since in the sample used about 58 % of the furfuraldehyde was due to the cellulosan in the cellulose and consequently would be unaffected by the treatments, the removal of encrusting polyuronide hemicelluloses must have been practically complete. This effect of chlorination in assisting the removal of hemicelluloses had not been previously reported. The experiments described below are a further investigation of this point.

#### EXPERIMENTAL.

All plant materials employed were previously ground to pass a 60-mesh sieve. Extractions with sodium sulphite were carried out by boiling gently with 100 ml. solution for 20 min., 2-3 g. material being taken initially for each experiment. The residue was filtered on cloth while hot, and after the final treatment thoroughly washed with warm water. Gaseous chlorinations were given by passing a steady stream of the gas over and through the material suspended on a cloth fastened over a small Büchner funnel, suction being applied throughout. The time of contact with the gas was 10 min. in all cases. Chlorinations in solution were carried out by suspending the material in 100 ml. water and adding 5 ml. dilute sodium hypochlorite (about 3 % available Cl) and 2 ml. 20 %  $\text{H}_2\text{SO}_4$ . After standing for 10 min. the residue was filtered off but not extensively washed before taking up in sulphite.

All determinations of total loss were made in duplicate or triplicate, the dried residues being bulked, reground and divided for duplicate determinations of furfuraldehyde yield and lignin content after hydrolysis for 1 hour with 5 %  $\text{H}_2\text{SO}_4$  [Norman and Jenkins, 1934].

##### 1. *Extraction of wheat straw (J. G. S.).*

The removal of lignin and encrusting polyuronides by hot sulphite solutions was studied with and without alternate exposure to chlorine gas or chlorine in solution. The results are summarised in Table I. One treatment with sulphite

Table I. *Removal of polyuronides and lignin from wheat straw.*

All results calculated on 100 g. original straw. Straw contained 51.91 % cellulose, 14.95 % lignin (after hydrolysis). Furfuraldehyde from cellulose 9.59 %.

	No. of treat- ments	Residue	Total furfur- aldehyde	Polyuronide furfur- aldehyde	Lignin (after hydrolysis)
A. 3 % sulphite alone	—	100.0	17.61	8.0	14.95
	1	83.2	17.38	7.8	10.60
	2	81.4	17.21	7.6	9.75
	3	77.8	17.02	7.4	9.39
	4	75.4	16.93	7.3	8.54
	6	72.2	15.69	6.1	7.14
B. Chlorine gas then 3 % sulphite	1	78.6	15.70	6.1	6.79
	2	73.2	14.66	5.1	3.82
	3	66.9	12.34	2.7	2.46
	4	58.9	11.00	1.4	2.04
	6	55.3	10.02	0.4	1.36
C. Chlorine in solution then 3 % sulphite	1	76.4	15.67	6.1	7.49
	2	70.5	14.05	4.5	5.95
	3	66.1	13.62	4.0	3.85
	4	58.8	10.95	1.4	2.53
	6	52.7	9.60	0.0	1.39
D. Chlorine gas then 1.5 % sulphite	1	79.3	15.46	5.9	6.61
	2	73.3	15.25	5.7	4.03
	3	69.8	14.32	4.7	2.76
	4	64.4	13.70	4.1	2.18
	6	59.3	11.95	2.4	1.60

alone removed about a third of the lignin and only a little of the polyuronides as followed by the difference in total furfuraldehyde yield and furfuraldehyde due to cellulosan. Further treatments produced a slow fall in both, but at the end of six treatments nearly half the lignin remained together with 76% of the polyuronides. Wheat lignin may, therefore, be slowly removed by neutral 3% sulphite. The polyuronides of this material, however, do not go into solution to any great extent under the same treatment. Solutions of neutral sulphite under pressure have been employed for the delignification of wood for pulps, but the results obtained have not been encouraging, as high pressures are necessary for the satisfactory removal of lignin.

By exposure to chlorine gas before each extraction with sulphite (Table I, B). the removal of lignin was, as would be expected, greatly expedited. The hemicelluloses were affected equally and rapidly came into solution also. One chlorination and sulphite extraction resulted in the removal of more lignin and as much of the polyuronic hemicelluloses as six sulphite treatments alone. The results obtained after chlorination in solution (Table I, C) were almost identical with those for gaseous chlorination. Substitution of 1.5% sulphite for 3% sulphite following treatments with chlorine gas was not significantly different in so far as the removal of lignin was concerned but resulted in a less complete extraction of the hemicelluloses. It is therefore important in cellulose determinations to use sulphite of 3%, as with a lower concentration the material might give no colour test for lignin and yet contain appreciable amounts of encrusting polyuronides unremoved.

These experiments show that the extraction of the polyuronides with sodium sulphite cannot be effected without chlorination. Further, by submitting the same material to one chlorination and then following with successive sulphite extractions without additional exposures to chlorine, the removal of the hemicelluloses was shown to be dependent on the removal of lignin. About 30 g. wheat straw were thoroughly soaked in water for some hours, after which dilute hypochlorite and acid were added to effect chlorination in the usual way for 10 min. The residue was filtered and boiled for 20 min. with 3% sulphite. After thorough washing it was dried, weighed and analysed. Small portions were subsequently given 1, 2, 3 and 5 further extractions with 3% sulphite. The results of these treatments are given in Table II. The removal of lignin by the successive sulphite treatments was slow and the loss of polyuronic hemicellulose not more rapid despite the intervention of an initial chlorination.

Table II. *Effect of one chlorination and successive sulphite extractions on the removal of polyuronides and lignin from wheat straw.*

All results calculated on 100 g. original straw.

No. of treatments*	Residue	Total furfuraldehyde	Polyuronic furfuraldehyde	Lignin (after hydrolysis)
—	100.0	17.61	8.0	14.95
1Cl. 1SO <sub>3</sub>	77.0	15.16	5.6	8.26
1Cl. 2SO <sub>3</sub>	73.0	14.94	5.4	7.62
1Cl. 3SO <sub>3</sub>	72.3	14.78	5.2	7.43
1Cl. 4SO <sub>3</sub>	70.6	14.59	5.0	7.16
1Cl. 6SO <sub>3</sub>	68.1	13.76	4.2	6.46

\* 1Cl. 1SO<sub>3</sub> indicates one chlorination followed by one sulphite extraction.

The effect of extraction with sodium sulphite under pressure with and without previous chlorination was tested. Two samples of straw, 7.5 g. each, were

soaked overnight in water. To one sample sodium sulphite was added to give 250 ml. of 3 % concentration. The other was made up to 200 ml. with water and 2 ml. concentrated sodium hypochlorite were added followed by 4 ml. 20 %  $\text{H}_2\text{SO}_4$ . After standing for 1 hour the residue was filtered off and suspended in 250 ml. 3 % sulphite solution. Both sulphite solutions were then autoclaved for 1 hour at 42 lb./sq. in. (144°). The residues were weighed and analysed as usual. The results are given in Table III.

Table III. *Effect of sulphite extraction of wheat straw under pressure with and without previous chlorination.*

All results calculated on 100 g. original straw.

Treatment	Residue	Total furfur-aldehyde	Furfur-aldehyde from polyuronide	Lignin after hydrolysis
Untreated	—	17.6	8.0	14.95
Sulphite alone	58.8	9.7	1.4	2.8
Chlorination followed by sulphite	59.0	10.4	1.6	3.2

Extraction with sulphite under pressure was clearly far more effective in the removal of lignin than prolonged boiling at 100°. Previous chlorination had no effect in increasing the extraction of lignin under these conditions and even reduced it slightly. This was possibly due to a small reduction in the concentration of the sulphite by the chlorine held in the sample.

### 2. *Extraction of mature meadow hay.*

The removal of lignin and polyuronide hemicelluloses from a sample of hay was studied in a similar manner. The results of analyses on this mixed material are given in Table IV. As in the case of wheat straw, a portion of the lignin went

Table IV. *Removal of polyuronides and lignin from hay.*

All results calculated on 100 g. dry material. Hay contained 44.79 % cellulose, 12.96 % lignin (after hydrolysis). Furfuraldehyde from cellulose 8.26 %.

Treatment	No. of treatments	Residue	Total furfur-aldehyde	Polyuronide furfur-aldehyde	Lignin (after hydrolysis)
A. 3 % sulphite alone	—	—	14.59	6.3	12.96
	1	72.09	13.21	4.9	9.65
	2	70.20	12.95	4.7	9.05
	3	69.17	12.64	4.4	9.00
	4	64.48	11.38	3.1	7.89
	5	64.31	11.24	3.0	7.88
B. Chlorine in solution then 3 % sulphite	1	69.46	13.07	4.8	8.44
	2	66.11	12.61	4.4	6.63
	3	60.02	11.23	3.0	4.06
	4	54.18	9.64	1.4	2.82
	5	48.35	9.06	0.8	2.26

into solution on treatment with sulphite alone and was accompanied by some of the polyuronide hemicelluloses. On further treatment with sulphite small quantities of both were removed, so that after six extractions a little over half the polyuronide material and less than half the lignin had gone. Chlorination greatly increased the rate of removal of both groups, the losses running almost parallel.

### 3. *Extraction of barley straw.*

Results of a similar nature were obtained in another series in which barley straw was subjected to the same extractions (Table V). Again a portion of the

lignin was readily removed by boiling with sulphite. Chlorination vastly increased the removal of polyuronide hemicelluloses as well as that of lignin.

Table V. *Removal of polyuronides and lignin from barley straw.*

All results calculated on 100 g. dry material. Barley contained 48.60 % cellulose, 16.44 % lignin (after hydrolysis). Furfuraldehyde from cellulose 7.37 %.

Treatment	No. of treat- ments	Residue	Total furfur- aldehyde	Polyuronide furfur- aldehyde	Lignin (after hydrolysis)
A. 3 % sulphite alone	—	—	18.69	11.3	16.44
	1	81.33	16.34	9.0	11.05
	2	79.34	15.98	8.6	10.24
	3	76.90	15.61	8.2	9.35
	4	75.40	15.00	7.6	8.87
	6	72.47	13.53	6.2	7.79
B. Chlorine in solution then 3 % sulphite	1	77.65	14.77	7.4	8.38
	2	69.42	13.75	6.4	6.03
	3	61.65	11.40	4.0	3.03
	4	59.66	10.90	3.5	2.68
	6	54.23	9.74	2.4	1.61

#### 4. *Extraction of oak wood.*

Samples of oak, previously extracted with alcohol-benzene for the removal of resinous matter, were extracted in a similar manner.

Table VI. *Removal of polyuronides and lignin from oak.*

All results calculated on 100 g. alcohol-benzene-extracted wood. Wood contained 53.85 % cellulose, 22.26 % lignin (after hydrolysis). Furfuraldehyde from cellulose 9.21 %.

Treatment	No. of treat- ments	Residue	Total furfur- aldehyde	Polyuronide furfur- aldehyde	Lignin (after hydrolysis)
A. 3 % sulphite alone	—	100.0	13.37	4.2	22.26
	1	90.0	12.67	3.5	21.48
	2	88.6	12.64	3.4	21.52
	3	86.8	12.40	3.2	21.10
	4	86.4	12.10	2.9	21.25
	6	84.9	11.95	2.7	20.95
B. Chlorine in solution then 3 % sulphite	1	86.6	12.12	2.9	18.72
	2	77.3	10.65	1.4	14.25
	3	71.2	10.18	1.0	11.56
	4	62.1	9.24	0.0	7.01
	6	59.2	8.98	—	4.12

The results (Table VI) indicate certain differences between this wood and the other materials previously examined. The ratio of lignin to hemicellulose was much greater in the wood and was probably about 2, whereas in the straws the ratio was certainly less than unity. It would not be expected therefore that the removal of lignin and hemicelluloses from wood would run so closely parallel as in the other materials. Chlorination followed by sulphite extraction produced a rapid removal of both groups, but, as judged by furfuraldehyde yield, all the polyuronide hemicellulose material had gone into solution after four treatments although nearly a third of the lignin still remained. Again, contrary to the observations on straws, very little oak lignin went into solution on treatment with sulphite alone. On the other hand, about a third of the polyuronide material was removed by six successive sulphite extractions. In the case of this wood there seems to be a possibility that the association between hemicelluloses and lignin may be ruptured slowly by prolonged boiling with sulphite, without the lignin

itself coming into solution, a process presumably dependent on the ease of sulphonation of the lignin molecule. Because of the excess of lignin over hemicellulose, only a portion would be likely to be involved in such an association.

#### 5. *Extraction of silver fir wood.*

This wood, being a gymnosperm, has a much lower pentose content than the oak, and in consequence, the furfuraldehyde yield may not be such a satisfactory indication of the encrusting hemicelluloses. The results obtained (Table VII) are similar in character to those given by other materials. As in the case of oak, very little lignin went into solution in sulphite alone.

Table VII. *Removal of polyuronides and lignin from silver fir.*

All results calculated on 100 g. wood. Wood contained 53.83 % cellulose, 29.26 % lignin (after hydrolysis). Furfuraldehyde from cellulose 2.61 %.

Treatment	No. of treatments	Residue	Total furfur-aldehyde	Polyuronic furfur-aldehyde	Lignin (after hydrolysis)
A. 3 % sulphite alone	—	100.0	5.49	2.9	29.26
	1	94.9	5.34	2.7	27.30
	2	94.4	5.34	2.7	27.83
	8	90.9	5.04	2.4	25.83
B. Chlorine in solution, then 3 % sulphite	1	93.3	5.00	2.4	24.05
	2	84.5	4.50	1.9	16.89
	3	75.1	4.15	1.5	10.41
	4	69.2	3.73	1.1	6.96
	5	66.1	3.49	0.9	1.21
	6	60.4	3.03	0.4	0.31
	8	58.0	3.19	0.6	0.12

#### 6. *Modification of the material before extraction.*

Lignin, either isolated or *in situ*, is rapidly and extensively oxidised by a dilute solution of sodium hypochlorite, as will be shown in another communication later. Samples of two materials were treated for 16 hours at room temperature with dilute sodium hypochlorite of strength 0.75 % available chlorine, 100 ml. being used for 2.5 g., and in this way the lignin content was much reduced (Table VIII). A fall in the yield of furfuraldehyde indicated that there

Table VIII. *Removal of polyuronides after partial oxidation of lignin.*

All results expressed on the basis of 100 g. dry original material.

Material	Treatment	Residue	Total furfur-aldehyde	Polyuronic furfur-aldehyde	Lignin (after hydrolysis)
Barley straw	Untreated	100.0	18.69	11.3	16.44
	Oxidised with NaOCl	78.7	15.87	8.5	6.36

	3 % sulphite extraction of original material	72.1	13.21	4.9	9.65

was some accompanying loss of hemicelluloses. Whether this was due to oxidation or to simple extraction by the slightly alkaline solution is not known, though the latter is more probable. However, one sulphite extraction following on the

oxidation process removed considerably more of the polyuronide material than if given directly on the original material. This would suggest that the removal of lignin by oxidation liberated a certain amount of hemicellulose which was then free to dissolve in the sulphite.

Experiments were made to determine whether the apparent association between hemicelluloses and lignin was affected by a pre-treatment with cold alkali. Such a treatment, of course, extracts a certain amount of both constituents, but that remaining was not appreciably more susceptible to extraction either by sulphite alone or by sulphite following on chlorination.

Aqueous extractions following chlorination were found to be nearly as effective in the removal of the hemicelluloses as sulphite treatments, but far less effective, as would be expected, in the removal of lignin.

#### DISCUSSION.

Sufficient evidence has been presented to show that the removal of hemicelluloses from plant materials on extraction with sulphite solution is affected by previous chlorination to almost the same degree as is that of the lignin, for which the process was especially designed. Three explanations are possible. (1) That the hemicelluloses and lignin exist in some form of combination, and that the solution of the hemicelluloses depends therefore upon the rupture of the linkage. Rupture may be brought about slowly by boiling with sulphite or rapidly by chlorination. (2) That the hemicelluloses and lignin are not combined and chlorination has a specific effect on the hemicelluloses rendering them soluble. (3) That the hemicelluloses and lignin are not combined and that the removal of hemicelluloses is mechanically and physically hindered by the presence of an insoluble layer of lignin, only removed by chlorination. Of these three possibilities the first, though not hitherto demonstrated, appears the most likely. To the second may be raised the objection that a non-reducing polysaccharide is not known to undergo any reaction upon brief treatment with a halogen. Further, when the lignin content was very much reduced by oxidation with  $\text{NaOCl}$ , one sulphite treatment extracted considerably more of the hemicellulose material than if this pre-treatment were not given. The third alternative is not in accordance with present views on the structure of the cell wall.

The theory of a combination between lignin and encrusting hemicelluloses finds further support in the changes in solubility of the latter after isolation. Whereas hemicelluloses are only removed from the tissues by agents which also will dissolve lignin and rupture the linkage, after isolation they are frequently soluble in hot water, or even slowly in cold water. It should be stated that Ritter and Kurth [1933] have shown that the polyuronide fraction of maple wood carries about one-sixth of the total methoxyl groups and all the acetyl groups present in the wood. The removal of some of these substituent groups in the ordinary process of isolation might also be a contributory factor in the observed change in solubility mentioned above.

If lignin and hemicelluloses occur in some form of combination, as this work indicates, there is the possibility of both groups existing in two conditions, attached and unattached, depending on the relative quantities of each present. Further, it implies that lignin should not be considered so inert in the plant as it is usually regarded.

## SUMMARY.

The removal of polyuronide hemicelluloses from plant materials and woods is not easily effected by dilute sulphite solutions unless the material is given a previous chlorination. Some form of combination or association between lignin and this type of hemicellulose is probable, since the extraction of the latter depends on a treatment effecting the solution of the former.

# CCLXVIII. ENZYME FORMATION AND POLYSACCHARIDE SYNTHESIS BY BACTERIA.

By EVELYN ASHLEY COOPER (Leverhulme Research Fellow)  
AND JOHN FREDERICK PRESTON.

*Chemical Department, The University of Birmingham.*

*(Received August 1st, 1935.)*

It is only comparatively recently that precise knowledge has been obtained in regard to the important problem of polysaccharide synthesis by bacteria. This advance has been due to the work of Hibbert and co-workers [1930-34], who succeeded in isolating in the pure state and also on a large scale the polysaccharides formed by the activity of the micro-organisms *B. mesentericus*, *B. subtilis*, and *Acetobacter xylinum*, and ascertaining their chemical structure.

The polysaccharides synthesised by the closely related organisms, *B. mesentericus* and *B. subtilis* from sucrose and raffinose [1930; 1931, 1, 3; 1932] were found to be identical in chemical nature and to be "fructosans" of the laevan type. These laevans, consisting entirely of fructofuranose units are formed synthetically by the activity of a bacterial enzyme through the condensation of molecules of fructofuranose liberated in the nascent state in the initial hydrolysis of the sucrose and raffinose. The foregoing organisms were thus only able to produce a polysaccharide from carbohydrates, *e.g.* sucrose and raffinose, containing fructofuranose units; and such sugars as maltose, lactose, glucose, fructose (fructopyranose) were found to be unsuitable starting materials for synthesis. *Ac. xylinum* (the sorbose bacillus) synthesised cellulose [1931, 2, 4; 1934] from various carbohydrates and polyhydric alcohols, and it was discovered that the forms of cellulose produced by bacterial synthesis from glucose, fructose, galactose, sucrose, mannitol and glycerol were chemically identical, and also identical with cotton cellulose.

The experimental work described in the present paper deals mainly with the problem of enzyme formation and polysaccharide synthesis by (1) bacteria related to *B. mesentericus* and (2) bacteria pathogenic to plants. Apart from the work of Ruhland [1906], no systematic researches appear to have been carried out, so far, in connection with polysaccharide formation in the latter group of micro-organisms.

Ruhland studied the synthetic activities of *B. spongiosus*, an organism causing disease in cherry trees in Germany, and stated that a pentosan of an araban type was formed by the growth of this organism in sucrose and raffinose agar media. On account, therefore, of the possible interest of the subject in plant pathology, and also because of the chemical interest of the phenomenon of pentosan formation by a micro-organism, an investigation on polysaccharide synthesis by plant pathogens has been carried out. Furthermore, very little information is available concerning the rôle of synthesising enzymes, the nutritional conditions essential for their formation in bacteria and also their activity. An investigation of the biochemical conditions influencing the develop-

ment and activity of the synthesising enzymes in bacteria has therefore been undertaken, and the results obtained have been correlated with corresponding observations made with the hydrolytic enzymes, invertase and diastase.

#### METHODS OF INVESTIGATION.

The general procedure consisted in growing the organisms at 37° or 30° according to the optimum temperature of the species in a sugar-peptone-salt medium of the following composition.

##### *Medium I [Hibbert et al., 1930].*

			%
Sucrose or other carbohydrate	...	...	10
Peptone	...	...	0.1
Sodium phosphate ( $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ )	...	...	0.2
Potassium chloride	...	...	0.5

The preliminary experiments were carried out on a small scale in sterilised test-tubes or conical flasks. To avoid decomposition of the carbohydrates in consequence of boiling with the peptone, the sugar solutions were initially made up to 20 % strength with distilled water only and sterilised by intermittent steaming for 30 min. on three successive days. The peptone-phosphate-salt mixture was made up separately to double strength and similarly sterilised. The two media were then transferred by means of sterile pipettes with aseptic precautions and mixed in equal volume, thus giving a resulting medium of the above composition. The following carbohydrates and polyhydric alcohols were employed in order to test the capacity of the organisms to synthesise polysaccharides: sucrose, raffinose, maltose, lactose, galactose, glucose, fructose, mannose, arabinose, xylose, mannitol, glycerol. Raffinose being less soluble was used in 7.5 % concentration.

The organism under investigation was first cultivated in the sucrose-peptone medium (10 ml.) by transferring a small amount of the growth from the agar stock culture and incubating at the optimum temperature for 48 hours. One drop of this culture was then introduced by means of a platinum loop into each of the carbohydrate media employed, and these were then incubated for a period of 10 days. Vigorous growth usually took place, but notwithstanding the turbidity due to growth, where polysaccharide synthesis had occurred, it was generally possible to detect the bluish opalescence characteristic of a colloidal solution. The cultivations were then filtered through glass-wool or filter-paper, to remove the gross bacterial masses, and allowed to flow into three times the volume of methyl or ethyl alcohol. If a polysaccharide had not been produced, only a slight turbidity resulted, but where synthesis had taken place a white precipitate was thrown down. The supernatant liquid was poured off, the polysaccharide product dissolved in a small volume of water and reprecipitated twice with alcohol to remove adherent sugar and mineral matter. It was then weighed and examined by chemical methods discussed later in this paper.

An investigation of the influence of various carbon compounds on polysaccharide formation by *B. mesentericus* and other organisms from sucrose was first undertaken (a) to throw light on the conditions essential for the formation of the synthesising enzyme, (b) to ascertain whether new polysaccharide derivatives could be obtained by the linking of other sugars with the nascent fructofuranose. Culture media were therefore prepared, consisting of the usual 10 % sucrose-peptone-salt constituents, but containing in addition 7.5 % concentrations of one of the following compounds: glycerol, mannitol, arabinose, rhamnose, galactose, mannose, lactose, maltose. *B. mesentericus*, *B. megaterium*, or

the plant-pathogen, *Ps. pruni*, was subcultured into these media, and incubation was continued for 10 days. The results obtained were unexpected; maltose and mannitol increased growth and polysaccharide formation, whilst glycerol, rhamnose, arabinose and mannose entirely inhibited both these functions, and galactose slightly inhibited them. The mechanism of inhibition has been especially studied in the cases of mannose and arabinose. At first it was supposed that these inhibiting substances either suppressed the formation or retarded the activity of the invertase normally secreted by the organisms, thus preventing the hydrolysis of sucrose and formation of monosaccharides for growth and polysaccharide synthesis. This view had a certain measure of support by analogy with the results of some preliminary observations concerning the influence of certain carbon compounds on the diastatic action of *B. megaterium*. This organism was cultivated in a basal medium, containing 0.2% peptone, 0.2% sodium chloride, 0.2% starch, to which varying concentrations of polyhydric alcohols from 0.5% to 4% could be added. The diastatic action was measured by the incubation period at 37° necessary for the disappearance of the starch and intermediate dextrans in the culture media, as indicated by the absence of a blue or red colour when a drop was removed and mixed with iodine solution on a tile. It was found that glycerol, mannitol and sorbitol inhibited diastatic action when present in the above concentrations, whilst glycol and erythritol, and also sucrose, glucose, galactose, mannose and arabinose were without effect.

In the absence of the alcohols hydrolysis of the starch was complete within 48 hours, but in the presence of glycerol, mannitol or sorbitol 96 hours were usually necessary. The inhibitory action of glycerol and mannitol was still observed in the presence of phosphate buffer ( $p_H$  7.5), and was thus not due to the deleterious influence of  $p_H$  changes on growth or enzymic activity.

In some further experiments the organism was first of all grown in the peptone-medium for 48 hours in the absence of starch and polyhydric alcohols. These were then introduced into the cultures together with chloroform or a crystal of thymol to inhibit growth, and diastatic action was measured. It was now found that the presence of the alcohols was without effect.

The organism was next grown in the peptone medium containing the polyhydric alcohol and phosphate buffer, but without starch. The latter was then added after 48 hours' incubation together with thymol, and diastatic action was determined. It was now found that the cultures containing the mannitol or glycerol hydrolysed the starch less rapidly than the control peptone culture.

These experimental results lead to the conclusion that the inhibitory effect of the polyhydric alcohols on diastatic power is not due to any interference with the actual activity of the diastatic enzyme but is associated with a depressing action on the process of formation of the enzyme in the bacterial cells. The influence of mannitol and glycerol on the rate of growth of *B. megaterium* was therefore next investigated both by observing the turbidity of the cultures and by actual enumeration. It was found that in the initial stages of the growth of the cultures multiplication of the organism was somewhat inhibited, but in the later stages growth was increased in the presence of the alcohols, and the results are difficult to interpret.

The observations made on diastatic action, however, suggested the possibility that the inhibitory effect of mannose and arabinose on polysaccharide formation already referred to might be due to their interference with the invertase secreted by the organism, and this hypothesis was tested by employing a culture medium in which the sucrose was entirely replaced by glucose (10%), and also by using

the peptone-salt medium free from either sucrose or glucose, and containing only the inhibitory carbohydrate under examination. It was found that arabinose and mannose were still strongly antagonistic to growth. These results pointed to the conclusion that their inhibitory power was not due to interference with the invertase function, since inhibition still took place in the absence of sucrose, and it would seem to be of the nature of antiseptic action. In this connection it is interesting to note that Huang [1934] has found that mannose is more toxic to fibroblasts cultivated *in vitro* than is glucose, fructose or galactose. This interpretation is supported by the further observations that arabinose, glucose and galactose and also mannitol and glycerol in 2% concentration had no influence on the rate of hydrolysis of 2% sucrose by *B. megaterium*. The method employed consisted in estimating the increase in the amount of reducing sugar after incubation at 37° for 3 days.

We have also investigated the effect of the presence of various carbohydrates on the formation of cellulose from sorbitol by *Ac. xylinum*. The sorbose bacillus was grown in yeast-water, to which had been added 5% of sorbitol, at 20° for 10 days. The yeast-water was prepared by boiling 1 part of yeast by weight with 10 parts of water for 10 min., and filtering through a folded filter. 50 g. of sorbitol were then dissolved in 720 ml. of the yeast extract, 182 ml. of distilled water were added, followed by 40 ml. of red wine and 8 ml. of glacial acetic acid, and the mixture was sterilised by boiling for 10 min. The culture medium was distributed in large Erlenmeyer flasks to a height of 2 cm. to ensure good aeration and again sterilised. The sorbose bacillus was then subcultured from the stock culture into the flasks by means of a platinum loop, and the flasks were allowed to stand at 20° for 10 days. The red wine was added to supply alcohol to the organism, in order to encourage growth, and the acetic acid was added to inhibit the growth of any contaminating moulds, which might possibly gain access [Schlubach and Vorwerk, 1933; Reichstein and Grüssner, 1934].

After 10 days, a thick pellicle or membrane of cellulose was produced in the liquids. It was found that the addition of glucose, arabinose or mannose in 5% concentration prevented the formation of a cellulose membrane, whilst galactose and fructose increased cellulose formation. In some further experiments arabinose in 3%, and mannose even in 0.1%, concentration perceptibly inhibited the growth of the organism and polysaccharide formation in 5% sorbitol-yeast-water medium.

Hibbert *et al.* [1931, 2, 4] showed that *Ac. xylinum* formed cellulose readily from many carbon compounds, *e.g.* glycerol, fructose *etc.*, but in only relatively small amount from sucrose. This is explained by the observation of Hermann and Neuschul [1931] that the organism has only a limited capacity to invert sucrose, thus producing only small amounts of monosaccharide for synthesis to the polysaccharide. *Ac. xylinoides*, however, exerted a much more powerful invertase action, and it was thus of interest to compare the synthetical capacity of this organism in building cellulose from sucrose.

*Ac. xylinoides* was therefore cultivated in yeast-water media, containing respectively 5% sorbitol, glycerol or sucrose, at 20° for 10 days. In all cases a membrane was produced, and it was produced as strongly in the presence of sucrose as of either glycerol or sorbitol. A membrane was also formed from raffinose. The pellicles were collected and purified as before and retained for chemical examination and comparison with the corresponding material synthesised by the sorbose bacillus.

The possibility of synthesis of cellulose from fatty acids by *Ac. xylinum* has also been investigated. As this organism produces a small amount of cellulose

from yeast-water, a basal medium of the following composition was employed [Hibbert *et al.*, 1931, 2]:

- 1 g. asparagine,
- 5 g. potassium dihydrogen phosphate,
- 1 g. sodium chloride,

dissolved in 1 litre distilled water.

5% solutions of succinic, citric and malonic acids were prepared in this medium and the  $p_H$  was adjusted to 5.0 with *N* sodium hydroxide. Ethyl alcohol was added to 0.5% concentration and *Ac. xylinum* subcultured into the media, which were then allowed to stand at 20° for 3 weeks. No membranes were produced, although a control experiment with 5% glucose and sucrose yielded a delicate cellulose pellicle. The experiments showed that under these conditions *Ac. xylinum* was unable to synthesise cellulose from the fatty acids. Further experiments using 2% solutions of other acids, *e.g.* tartaric, maleic, sebacic, adipic and glutaric acids, also gave negative results.

*B. megaterium* was also unable to synthesise polysaccharides from fatty acids, *e.g.* 2.5% sodium acetate, malonate or succinate, nor did these substances influence the formation of polysaccharide from sucrose. The fatty acid salts also had no effect on diastatic activity in the case of *B. megaterium* grown in a peptone medium.

With the exception of the section of work dealing with *Acetobacter*, the conventional peptone medium (Medium I) has been employed throughout this investigation. It was now considered of interest to vary the form in which nitrogen was supplied in the media, as this change might influence the yield of polysaccharide produced and throw light on the question as to the nutritional conditions essential for the formation of the synthesising enzymes.

For this purpose the peptone was replaced by amino-acids, amides and amine-derivatives, 0.1% solutions being employed. The following results have been obtained:

In the cases of *B. megaterium*, *Ps. pruni* and *B. syringae* asparagine was quite as efficacious as peptone as a source of nitrogen for polysaccharide formation. The addition of asparagine (0.1%) to peptone, however, did not increase the yield of polysaccharide.

The following results were obtained with *B. megaterium*:

(1) Ammonium chloride, potassium nitrate, urea and a tetraethylammonium salt were not suitable sources of nitrogen, no polysaccharide at all being produced and no growth when these substances were used in the place of peptone.

(2) Only very slight growth and formation of polysaccharide occurred with glycine as source of nitrogen.

(3) *D*-Alanine and *L*-leucine were generally as efficacious as peptone for the synthesis of the polysaccharide, but not consistently so, as occasionally the yield of polysaccharide was distinctly less than that obtained when peptone was employed.

It is seen that growth and polysaccharide formation both depend fundamentally on the source of nitrogen supplied, but whenever growth occurred there was evidence of the simultaneous production of the synthesising enzyme. Analogous results were obtained in the case of the hydrolytic enzymes, diastase and invertase, secreted by *B. megaterium*, diastatic action being measured by the colour changes with iodine and formation of reducing sugar in a starch medium, and invertase activity by the production of reducing sugar from

sucrose. Whenever growth occurred, formation of the enzymes took place, as in the case of the synthesising enzyme.

The organism *Achromobacter viscosum*, however, is much more limited in its growth capacity than *B. megaterium* as we have found that, whilst it develops satisfactorily in the sucrose-peptone medium, when the peptone is replaced by *l*-leucine growth is only slight, and growth does not take place at all when asparagine, glycine, *d*-alanine or synthetic alanine is employed as source of nitrogen.

The organisms so far employed have been mainly *B. mesentericus*, *B. megaterium*, and *Ps. pruni*. *B. mesentericus* was shown by Hibbert to form a polysaccharide of the laevan type, and we have now shown that a similar product is formed by *B. megaterium* and *Ps. pruni*. In both cases the polysaccharides after hydrolysis with acid yielded a sugar, which gave Selivanoff's reaction for fructose, formed glucosazone with phenylhydrazine and was laevorotatory (see Tables I and III).

It was thought that the investigation would be of greater interest if it were possible to study enzyme formation in organisms synthesising polysaccharides of wider physiological interest than fructosans, such as pentosans, dextrans and galactans. Organisms of three classes have therefore been studied in regard to their capacity to synthesise polysaccharides.

*A. Aerobic sporing organisms from soil, air and water.* Hibbert and co-workers showed that the polysaccharides obtained by the action of *B. mesentericus* and *B. subtilis* were of the laevan type, containing fructofuranose as the only sugar unit. We have carried out experiments with several related organisms and in some cases were able to isolate a polysaccharide.

*B. megaterium*, *B. mycoides*, *B. panis*, *B. ruminatus*, and an unidentified organism resembling *B. subtilis* and isolated from the gum of a cherry tree, all produced when cultivated in the sucrose-peptone medium a polysaccharide yielding only fructose on hydrolysis. As in the cases of *B. mesentericus* and *B. subtilis* other sugars used in the place of sucrose gave entirely negative results. The results with *B. mycoides* were somewhat variable, as this organism occasionally failed to yield a polysaccharide.

*B. tumescens*, on the other hand, consistently failed to synthesise a polysaccharide, probably because it is deficient in invertase. It is thus unable to hydrolyse sucrose and liberate the nascent fructofuranose, necessary for the synthesis of the polysaccharide.

Table I.

Organism	Specific rotations	
	Polysaccharide	Product of hydrolysis
<i>B. megaterium</i>	-47.0°	-91.5°
<i>B. mycoides</i>	-38.0°	-80.0°
<i>B. panis</i>	-37.0°	-87.0°

*B. Plant pathogens.* Investigations with these important organisms have been undertaken as already pointed out primarily on account of (1) the possible immunological significance of their specific polysaccharides, and (2) the chemical interest centred on the work of Ruhland [1906], who concluded that *B. spongiosus*, causative of cherry tree bacteriosis in Germany, produced a polysaccharide of an araban type from sucrose. We have not been able to obtain a culture of this particular organism, but have studied certain micro-organisms closely allied to *B. spongiosus* and also several other bacteria known to be

Table II. *Plant-pathogens.*

## (a) Organisms readily forming a polysaccharide from sucrose.

*Ps. pruni*  
*Ps. prunicola* (from plum and cherry trees)  
*Ps. mors-prunorum* (from plum and cherry trees) [Wormald 1930; 1932]

<i>B. barkeri</i>	<i>Ps. juglandis</i>
<i>B. cannaz</i>	<i>Ps. tumefaciens</i> , and also
<i>B. malvacearum</i>	the non-pathogenic
<i>B. phytophthorus</i>	<i>Radiobacter</i>

pathogenic to plants (Table II). From the results set out in Table II it will be seen that in quite a number of cases a polysaccharide was synthesised in a sucrose medium. With two organisms, *Ps. pruni* and *B. syringae*, raffinose was employed and also yielded a polysaccharide, but in every case all the other carbohydrates previously mentioned gave entirely negative results. The capacity to form a polysaccharide from sucrose (or raffinose) only and not from any other carbohydrate employed is thus a specific property of all the plant-pathogens so far found to exhibit synthetical activity. A few of these organisms, e.g. *B. caratovorur*, only occasionally yielded a polysaccharide product. The reasons for this variability, however, have not yet been investigated. A certain number of these pathogenic organisms, on the other hand, consistently failed to produce a polysaccharide from sucrose or any other carbohydrate under the experimental conditions. A typical case is that of *Ps. tumefaciens*, and it is interesting to note that the non-pathogenic form *Radiobacter* is apparently closely related with *Ps. tumefaciens* [Sager *et al.*, 1934], and is also deficient in synthetical power.

*Ps. tumefaciens* being of pathological importance in inducing a form of cancer in plants, it was considered that it would be of interest to investigate its action on the metabolism of other bacteria. Accordingly, the influence of *Ps. tumefaciens* on polysaccharide formation by other organisms has been studied. Cultures of *Ps. pruni*, *B. syringae*, *B. megaterium* in 10 % sucrose-peptone media were therefore set up, and into a certain number of these *Ps. tumefaciens* was introduced, incubation then being continued for 10 days. It was found that polysaccharide formation by the foregoing organisms was entirely suppressed in the presence of *Ps. tumefaciens*. However, it was subsequently observed that *B. coli* also interfered with the formation of polysaccharide by *B. megaterium* so that this is not specific to *Ps. tumefaciens*. It is of interest to note that when *B. megaterium* was cultivated in sucrose-peptone, the  $p_H$  changed from the initial value of 8 to 6.5, owing to the metabolic production of organic acids. In the presence of *Ps. tumefaciens* or *B. coli*, however, the  $p_H$  remained unchanged. The amount of reducing sugar produced by *B. megaterium* through the inversion of the sucrose was also diminished in the presence of these interfering organisms. It would appear therefore that the organisms inhibited the growth of each other when cultivated in mixed culture.

The polysaccharide products obtained in the above way were next examined chemically, with the following results:

(i) The polysaccharides themselves were nitrogen-free and without reducing action on Fehling's solution, but after hydrolysis with boiling dilute acids and neutralisation with NaOH marked reduction took place. Hydrolysis seemed to proceed rapidly, as the opalescence due to the colloidal state soon disappeared.

(ii) A portion of the acid solution (obtained by hydrolysing the polysaccharide with acid) was treated with solid sodium acetate and a few drops of phenylhydrazine, and the mixture heated in the water-bath for 20 min. Yellow crystals were deposited and were identified by microscopical examination and M.P. as glucosazone.

(iii) The polysaccharides gave Selivanoff's test when heated with resorcinol and HCl, suggesting the presence of fructose units in their molecules. Pentoses were shown to be absent by failure to obtain either the colour reactions or the absorption spectra tests with orcinol and phloroglucinol.

(iv) *Optical activity.* All the polysaccharides after hydrolysis with oxalic acid yielded a sugar, which had a specific rotation approximating to that of fructose.

Table III.

Organism	Specific rotations	
	Polysaccharide	Product of hydrolysis
<i>Ps. pruni</i>	-42.4°	-95.5°
<i>Ps. prunicola</i> (plum)	—	-96.5°
„ (cherry)	—	-98.0°
<i>Ps. mors-prunorum</i>	—	-92.5°
<i>Ps. aptatum</i>	—	-82.0°
<i>Ps. phaseoli</i>	—	-85.0°
<i>B. syringae</i>	-40.0°	-89.0°
<i>B. tabacum</i>	—	-80.0°

Ruhland [1906] carried out his experiments on solid media, and in view of his results with *B. spongiosus* we therefore repeated our work with *Ps. pruni* and *Ps. prunicola* [Wormald, 1930] using 10% sucrose-nutrient agar. After 10 days' incubation *Ps. pruni* had formed a hard horny growth on the surface of the agar, whilst that of *Ps. prunicola* was more fluid and gummy. The growths were carefully washed off with a little cold distilled water and the filtered washings poured into methyl alcohol. In the case of *Ps. pruni* only a small amount of an impure gummy material was isolated. Better results were obtained with *Ps. prunicola*, but even in this case the polysaccharide was less pure than when prepared in liquid media. The product, however, after hydrolysis yielded glucosazone with phenylhydrazine and gave Selivanoff's reaction. It was not pure enough, however, for measurement of optical activity; even after heating with acid it still gave a turbid solution. These preliminary observations pointed to the conclusion that the polysaccharides derived from the various plant-pathogens tested in this investigation were fructosans, i.e. contained fructose as the only constituent unit. There was no evidence that a pentosan was formed, as stated by Ruhland [1906] in the case of *B. spongiosus*.

Two of the polysaccharides (from *Ps. pruni* and *Ps. prunicola*) have been prepared on a large scale, in order to obtain more precise knowledge of their chemical nature. In the case of *Ps. pruni* experiments were therefore carried out to ascertain the optimum concentration of sucrose for polysaccharide synthesis. Concentrations of 5, 10, 15, 25 and 30% were used in the peptone-salt medium already mentioned. 30 ml. of each concentration were inoculated with a

48-hours' sucrose-peptone culture of *Ps. pruni* and incubated for 16 days at 37°. 10 ml. of each solution were then run into 35 ml. of methyl alcohol, the polysaccharide was allowed to settle down, the supernatant alcohol poured off and the residual polysaccharide dried at 37° for 1 hour and then in a vacuum over calcium chloride, and finally weighed.

Table IV.

Sucrose concentration %	Weight of polysaccharide per 10 ml.	
	8 days g.	16 days g.
5	0.038	0.065
10	0.069	0.118
15	0.114	0.177
25	0.145	0.134
30	0.189	0.392

The yield of polysaccharide thus increased as the concentration rose and the period of incubation was extended. In the large scale preparation 20 % sucrose was selected and 14 days' incubation.

Similar experiments were carried out to discover whether peptone was the most desirable source of nitrogen for polysaccharide synthesis. It was found that there was no advantage in substituting asparagine for peptone, or in supplementing the peptone supply with 0.1 % concentration of asparagine.

#### *Preparation of the polysaccharides.*

*Ps. pruni*. Seven litres of the 20 % sucrose-peptone-salt medium were distributed into large Erlenmeyer flasks and sterilised, inoculated with a 48 hours' culture of *Ps. pruni* (in sucrose-peptone), and incubated at 37° for a fortnight. The opalescent solution was then filtered and concentrated to 1/4 bulk under reduced pressure at 45°. The residual syrup was poured slowly with mechanical stirring into 2.5 volumes of methyl alcohol. The precipitated polysaccharide was dissolved in warm water and reprecipitated twice with methyl alcohol. It was then ground with alcohol to a fine powder, filtered, washed with alcohol and ether and dried in a vacuum desiccator. 146 g. of the polysaccharide were obtained, as a fine pinkish white powder free from reducing sugar.

A further 6 litres of 20 % sucrose-peptone medium was inoculated with *Ps. pruni*, and an additional amount of polysaccharide prepared to complete the chemical investigation.

*Ps. prunicola* [Wormald, 1930]. Six litres of 20 % sucrose-peptone medium were inoculated with this organism and incubated at 25° for 3 weeks. The polysaccharide was isolated by the same method as for *Ps. pruni*. The solutions after incubation were extraordinarily opalescent and the isolated polysaccharide was less soluble in water than that of *Ps. pruni*; yield 106 g.

A chemical investigation of these two apparently different polysaccharides is at present being undertaken by Prof. W. N. Haworth and Dr E. L. Hirst, and their chemical structure is being compared with that of the "laevan" synthesised by *B. mesentericus* and *B. subtilis*.

C. *B. coli* and related organisms. *B. coli* and *B. lactis aerogenes* failed to produce a polysaccharide from any of the sugar-peptone media previously mentioned. In the presence of calcium carbonate to prevent the accumulation of organic acids in the cultures, *B. lactis aerogenes* synthesised a small amount of

a polysaccharide product from sucrose and galactose [cf. Emmerling, 1900]. It was not possible to isolate a sufficient amount for chemical investigation.

An apparently similar organism [Beckwith, 1931; Sanborn, 1933] isolated from paper-slime also yielded an insignificant amount of polysaccharide in sucrose and galactose media.

The following organisms failed to form a polysaccharide under the foregoing experimental conditions: *Lactobacillus pentoaceticus*, *Staphylococcus cremoris viscosi*, *Achromobacter* sp. I., *Proteus vulgaris*, *B. macerans*.

#### SUMMARY.

1. Mannose and arabinose inhibit polysaccharide formation from sucrose by *B. mesentericus*, *B. megaterium* and *Ps. pruni*; and also by *Acetobacter xylinum* from sorbitol. This phenomenon seems to be due to a direct toxic effect on the cell and not to an interference with enzyme mechanism.

2. Glycerol, mannitol and sorbitol diminish the diastatic power of cultures of *B. megaterium*, and this inhibitory effect appears to be due to a depression in the rate of formation of the diastatic enzyme in the bacterial cell. The action of invertase on the other hand is unaffected.

3. *B. megaterium* and *Ac. xylinum* do not synthesise polysaccharides from fatty acids, and these in the case of *B. megaterium* are without effect on diastatic action.

4. The presence of peptone is not essential for polysaccharide formation from sucrose by *B. megaterium*, *B. syringae* and *Ps. pruni*, as this occurs as freely with asparagine, and usually with *d*-alanine and *l*-leucine, as sole sources of nitrogen. The synthesising enzyme can thus be formed in the presence of a single amino-acid, and this is also true for the formation of invertase and diastase by *B. megaterium*. With this organism on the other hand ammonium and tetraethylammonium salts, potassium nitrate, urea and glycine are not suitable sources of nitrogen for growth, enzyme formation or polysaccharide synthesis.

5. Bacteria pathogenic to plants [ref. Table II] in many cases synthesise polysaccharides when grown in culture media containing sucrose. The polysaccharides are of the fructosan type, containing fructose as the constituent unit, and appear to be analogous to the laevans formed by *B. mesentericus* and *B. subtilis*. So far no evidence has been obtained of the formation of dextrans or pentosans by plant-pathogens.

6. Several aerobic spore-forming organisms, related to *B. mesentericus* and *B. subtilis*, also form similar polysaccharide products.

7. Methods for the large scale preparation of the polysaccharides synthesised by the plant-pathogens, *Ps. pruni* and *Ps. prunicola* are described.

This research has been carried out during the tenure by one of us (E. A. C.) of a Leverhulme Research Fellowship.

The authors wish to express their thanks to Prof. W. N. Haworth and Dr E. L. Hirst, for their interest in the progress of the work; and also to Dr R. St John Brooks, Curator of the National Collection of Type Cultures; Dr H. Wormald, East Malling Horticultural Research Station; Prof. H. Raistrick, London School of Hygiene and Tropical Medicine; and Prof. A. J. Kluyver, Delft, for their help in obtaining the cultures of micro-organisms employed.

## CCLXIX. THE DISTRIBUTION OF CHOLINE.

By JOHN PALMER FLETCHER, CHARLES HERBERT BEST  
AND OMOND McKILLOP SOLANDT.

*From the Department of Physiological Hygiene, School of Hygiene,  
University of Toronto.*

*(Received August 1st, 1935.)*

INTEREST in the total choline content of animal and plant tissues has been aroused by recent investigations which have demonstrated the importance of choline as a dietary constituent. Previous estimates of the choline content of various tissues have been largely concerned with the determination of free choline [Alles, 1934; Guggenheim, 1924]. More recently there have been some attempts to measure free and bound choline separately. The methods used for the separation of free and bound choline are complex and tedious and the separation is apparently unnecessary for the purpose of dietetic experiments on normal animals. Consequently an attempt has been made to evolve a reasonably accurate and rapid method for the estimation of the total choline content of foods. The present paper is concerned with the details of the method devised and some of the results obtained with it. In addition to measuring the total choline content of many materials which have been incorporated in experimental diets for rats and dogs, the total choline content of the different tissues of the normal white rat was investigated.

### *Method.*

After careful consideration of all the chemical and biological methods for the estimation of choline it was decided that extraction, acetylation and assay of the resultant acetylcholine, using the isolated intestine of the rabbit, was the most advantageous method for the present purpose. A description of the method finally evolved may be divided into two parts. First, the digestion of the tissue, hydrolysis of choline-containing compounds and extraction and acetylation of the choline; second, the biological assay of the resulting acetylcholine.

### *Digestion and acetylation.*

The hydrochloric acid digestion used by Best and McHenry [1930] for the estimation of histamine in tissues has proved to be equally satisfactory for the determination of choline. This procedure breaks up the tissue, hydrolyses the choline-containing compounds and extracts the choline without destroying measurable amounts.

The technique finally adopted is as follows. 2-4 g. or more of fresh tissue or other material are rapidly weighed, minced and transferred to a 1-litre, round-bottomed flask; 20-40 ml. of 18 % HCl are then added and the mixture is boiled under a reflux condenser for 1 hour. After the boiling, 30-60 ml. of 95 % ethyl alcohol are added and the mixture of water, alcohol, acid and ester is removed *in vacuo* at about 90°. The residue is then washed with a small amount of 95 % alcohol and finally with absolute alcohol. The alcohol is removed *in vacuo* as before.

The residue, which has been carefully dried after the final washing with absolute alcohol, is then acetylated by the method of Abderhalden and Paffrath [1925]. 25 ml. glacial acetic acid and 5 ml. acetic anhydride are added to the residue and the mixture is boiled under a reflux condenser for 2 hours. The acetic acid and anhydride are then removed *in vacuo* at about 90° and the residue washed once with absolute alcohol. The acetylated residue is finally transferred to a volumetric flask by alternate small washings of alcohol and water until the total volume is 100 ml. This alcoholic solution is then diluted as required for assay.

Each step in this procedure has been tested by control experiments. The results of these experiments may be summarised as follows.

1. Many experiments on the destruction of choline during tissue autolysis suggest that no special precautions are necessary to prevent loss of choline between the time of death of the animal and the beginning of digestion of the tissue.

2. Varying the time of acid digestion from 30 to 90 min. caused no change in the value for the choline content of pancreas, suggesting that hydrolysis and extraction are complete in the shorter time.

3. Pure choline chloride is not measurably affected by 90 min. boiling with 18% HCl.

4. The method of acetylation repeatedly gave perfect acetylation of pure choline chloride solutions within the limits of accuracy of the biological assay.

5. Recovery of choline chloride added to tissues has always been complete within the limits of accuracy of the method.

#### *The biological assay.*

The isolated intestine of the rabbit was used as the test object for all assays. The intestine was mounted in a double intestine bath of conventional design and was bathed in Ringer-Tyrode's solution containing no glucose. It was found that better results were obtained with the duodenum than with any other part of the intestine. The intestine was definitely more reliable when removed under ether anaesthesia than when it was obtained from the dead animal. Purity of the Tyrode's solution and accuracy of temperature control are of course essential to satisfactory assaying.

All assays were done against a standard acetylcholine solution. The potency of this standard was frequently checked against fresh solutions and against freshly acetylated choline.

The accuracy of the biological assay was tested by assaying other dilutions of the standard against that ordinarily used. The results of these tests never showed an error greater than 10% and there did not seem to be any significant constant error. To attain this accuracy it is essential that doses of acetylcholine be chosen which will cause a contraction which is about 75% of the maximum. The concentration of acetylcholine necessary to elicit such a contraction varies considerably with different preparations but is usually one part of acetylcholine in  $1$  to  $3 \times 10^{-8}$  parts of solution.

In discussing the accuracy of the biological assay of the acetylated tissue residues, a great many interfering substances must be considered [Chang and Gaddum, 1933]. The prolonged heating and exposure to hydrochloric acid involved in the digestion process almost certainly destroy the adenosine derivatives [Drury and Szent-Györgyi, 1929], the substance P [Euler and Gaddum, 1931] and calliicin [Frey and Kraut, 1928; Kraut *et al.*, 1930]. Two samples

of creatinine were tested on the rabbit intestine. In doses up to 5000 times the usual dose of acetylcholine they caused no contraction at all.

The method of extraction used does not destroy histamine so that all the histamine from the tissues appears in the final solution. The rabbit intestine is very insensitive to histamine, but in order to be certain that the histamine would not have any significant effect on the results the histamine/acetylcholine ratio was determined by direct assay. Ratios were also obtained for choline and betaine. The results of these assays are given in Table I.

Table I. *Potency ratios determined with the isolated intestine of the rabbit.*

Acetylcholine	...	...	...	...	1
Acetyl- $\beta$ -methylcholine	...	...	...	...	1.7
Histamine	...	...	...	...	1,300
					2,700
					3,250
Choline	...	...	...	...	3,500
					4,200
					5,500
					6,100
Betaine	...	...	...	...	73,000

The figures given are the dose of the material required to cause a contraction of the intestine of the same magnitude as that caused by a unit dose of acetylcholine.

Among other substances which might interfere are acetate ions and ethyl alcohol. In most of the assays performed the amount of acetylcholine present was so great that, in the solution actually used for assay, the concentration of these substances was entirely negligible. In all cases where the concentration of acetylcholine was low enough to suggest some danger of interference, the solutions were assayed both before and after the addition of atropine to the perfusing fluid. In addition to the assay after atropine, some of the solutions were assayed before acetylation.

This combination of acid digestion, acetylation and assay on the isolated intestine of the rabbit seems to result in a method for the estimation of the total choline content of tissues which is quite specific for choline. The accuracy of the results obtained is probably limited chiefly by the accuracy of the biological assay in all cases where the amount of choline in the substance being examined is moderately large. Where the amount of choline present is very small the presence of interfering substances may produce an appreciable error. The maximum error in the assay of the acetylated tissue residues is apparently about  $\pm 15\%$  since duplicate assays have occasionally differed by almost 30%. With careful technique differences of this magnitude are very rarely encountered. In most of the present work duplicate assays were done on at least two samples of the material being analysed so that the average result should be correct within less than  $\pm 10\%$ .

## RESULTS.

The results which are reported here include the total choline content of the tissues of the normal white rat, of a variety of other animal tissues and of some materials used in experimental diets for rats and dogs. In addition, many other total choline determinations, done by the method which has been outlined, have been or will be reported in other communications. [Best *et al.*, 1934; Best, MacLean and Ridout, 1935; Best, Huntsman, McHenry and Ridout, 1935; McHenry, 1935, *etc.*]

*The total choline content of rat tissues.*

The results of the choline estimations on rat tissues are given in Table II. The rats used were all young adult white rats of the Wistar Institute strain. They had been reared at the Connaught Laboratories Farm on a commercial

28	Blood—Starved	3	4	22
	Fed	1	1	31

No difference was detected between the choline contents of tissues from male and female animals.

“balanced ration”. The average weight of the rats used was about 200 g. The rats were starved for 24 hours before use. In most cases corresponding tissues from several rats were pooled for the choline estimations.

The tissues are listed in the table in order of choline content. The results show that sperm-containing fluid from the seminal vesicles has the highest choline content of any tissue examined. This high choline content makes the values obtained for epididymis, ductus deferens and seminal vesicles of little significance since the result probably depends largely upon the content of seminal fluid.

The results obtained for the various parts of the central nervous system are quite in keeping with the high phospholipin content of these structures. It is interesting to note that the adrenal gland has approximately the same choline content as the other structures of nervous origin.

The average value given for the choline content of the liver is based on many more estimations than are the other results. In one experiment the livers of 24 rats were tested individually. These rats had been on an adequate mixed diet and were fully grown, averaging 250 g. in weight. The average choline content of the livers of these 24 rats was 260 mg. per 100 g. of fresh tissue.

The figure for the choline content of rat's pancreas may be too low since considerable difficulty was experienced in separating the pancreas from the connective tissue in which it is embedded.

The acetylated product from the lymph glands gave a very large, delayed contraction of the intestine after the contraction due to acetylcholine had subsided. This delayed contraction was not eliminated by atropine. Although the delayed contraction was not considered in calculating the result it is possible that the substance causing the contraction may have affected the result obtained.

The fat used in the choline estimations was all intra-abdominal fat and was obtained from around the kidneys, testicles or uterus and from the mesentery.

*The total choline content of other animal tissues.*

In Table III are given the total choline contents of a variety of tissues from animals other than the rat. Most of these results require no comment. The results for the choline content of dog stomach were obtained on material prepared for histamine assay [Gavin *et al.*, 1933]. This process involves neutralisation and filtration, which is not included in the ordinary technique for choline estimations, so the result may be slightly lower than would otherwise be the case.

Table III. *Total choline content of various animal tissues.*

Animal	Tissue	No. of samples	No. of determinations	Choline content mg./100 g.
Ox	Liver	1	2	270
	Pituitary—Anterior lobe	3	3	259
	Posterior lobe	3	3	217
	Pancreas	7	26	230
	Muscle	1	1	76
	Blood (defibrinated)	1	2	13
	Fat	2	3	0.5-2.6
Dog	Liver	4	19	230
	Stomach	2	4	90
	Blood (whole)	5	11	34
Pig	Pancreas	1	4	280
	Bacon (cured side bacon)	1	1	44
	Fat (from cooking bacon)	1	2	6
	Lard	1	2	1
Codfish	Muscle	2	2	78

The total choline content given for dog's blood is the average of 10 determinations on 5 samples of blood from 4 different dogs. The dogs were not starved before the blood was drawn. The results obtained ranged from 27 to 39 mg. of choline per 100 ml. of whole blood, with an average value of 34 mg. per 100 ml.

*The total choline content of various foods.*

The total choline content of a considerable number of foods has been investigated in a search for suitable ingredients for low-choline diets for rats and dogs. The results of the total choline estimations on some of these materials are given in Table IV. Those substances which are stated to contain no choline contain less than 0.1 mg. per 100 g. of material. The acetylated products from sugar and potato starch caused a smooth, rapid contraction of the intestine, not unlike that caused by acetylcholine, but this contraction was not diminished by atropine. Hence sugar and potato starch were considered to contain no significant amount of choline.

Table IV. *The total choline content of various cereals and other materials used in experimental diets.*

Material	Remarks	Choline content mg./100 g.
Flour	White wheat flour	140
Dog biscuit	Spratt's commercial grade	130
Oxo	Commercial meat extract	105
Rice	Polished	94
Milk powder	Dried, skimmed milk	90
Bovril	Commercial meat extract	78
Rice flour	Various commercial brands	73-65
Caseinogen	"Lister's prepared casein"	70
Bone meal	Commercial grade	30
Washed bran	—	28
Corn starch	--	25
Cheese	Canadian cheddar	19
Egg albumin	—	18
Rice starch	Various commercial brands	15-4.3
Butter	Fresh creamery butter	13
Caseinogen	British Drug Houses, "fat- and vitamin-free"	3.5
Egg white	White separated from hard-boiled eggs	2.0
Cellu flour	Ground cellulose	1
Edestin	Pfanstiehl, "pure"	1
Agar-agar	Various commercial brands	1.6-0.8
Crisco	Hydrogenated vegetable oils	0.4
Potato starch	Various commercial brands	0
Cane sugar	Various commercial brands	0
Mazola	Refined corn oil	0
Olive oil	--	0

Table V. *Total choline content of vitamin concentrates and vitamin-rich foods.*

Material	Remarks	Choline content mg./100 g.
Baker's yeast	Dried and powdered	270
Brewer's yeast	Dried and powdered	240
Radiomalt	-	64
Turnip	Fresh - used as source of vitamin C	42
Vitamin B <sub>1</sub> concentrate	Prepared according to method of Minnersley and Peters (4 samples)	22-8
Cod-liver oil concentrate	Vitamin A-500,000, vitamin D-3,000 International Units per g.	14
Tomato juice	Various commercial brands	9.8-6.6
Vitamin E oil	Unsaponifiable matter of wheat germ	4.0
Vitamin B <sub>1</sub> concentrate	Fuller's earth adsorbate from an extract of rice polishings	1.2

In Table V are given the total choline contents of a variety of vitamin-rich foods and vitamin concentrates which were investigated in connection with the preparation of the diets low in choline.

#### SUMMARY.

A method for the estimation of the total choline content of tissues is described. The method consists of digestion of the tissue with hydrochloric acid, acetylation of the extracted choline and assay of the resulting acetylcholine on the isolated intestine of the rabbit. The use of the hydrochloric acid digestion is the only novel part of the method. Acetylation and assay are carried out by well established procedures.

The total choline contents of the various tissues of the normal white rat, of several tissues from other animals and of many dietary constituents of both animal and vegetable origin have been determined by this method.

## CCLXX. METABOLISM OF TISSUES GROWING IN CULTURE.

### VI. EFFECT OF RADIUM ON THE LACTIC DEHYDROGENASE AND ARGINASE SYSTEMS OF EMBRYONIC TISSUE.

By BARBARA ELIZABETH HOLMES.

*From the Sir William Dunn Institute of Biochemistry, Cambridge.*

*(Received August 12th, 1935.)*

IN an earlier paper the effect of  $\gamma$ -radiation on the metabolism of tissue growing in culture was described [Holmes, 1933]. It was found that whereas the breakdown of sugars (glucose, galactose and laevulose) was considerably inhibited in the irradiated tissue, the production of ammonia and urea was not altered. The irradiation given was roughly estimated to be sufficient to cause the death of the tissue about 7 days after the dose of  $\gamma$ -rays had been given. It will be remembered [Spear, 1930] that the dose of  $\gamma$ -rays required to cause instantaneous death is far greater than that required to cause delayed death, and within limits, the length of time the cultures will live after irradiation depends upon the dose given. This curious fact makes the study of the metabolism of the tissues during the intermediate period particularly interesting, as it is possible that it may give some indication of the damage the cells have received. During the intermediate period growth and outwandering of the cells may continue normally for some time. Our cultures were only kept for 48 hours, and during this time the extent of outwandering of cells from the culture was not lessened, and the gross microscopical appearance (chromosomes not examined) was little altered. It therefore seemed that the mechanisms responsible for sugar breakdown were particularly sensitive to  $\gamma$ -rays under our conditions, being affected before the movement of the cells was inhibited and before nitrogenous metabolism was altered. It should be added that cell division was not taking place in any of the cultures (control or irradiated), but merely outwandering of sheets of epithelial cells and some fibroblasts, and that this outwandering had previously been found to be accompanied by ammonia and urea formation in the cultures [Holmes and Watchorn, 1927].

On the other hand, Crabtree [1932] found that aerobic and anaerobic glycolysis of tissues in glucose-bicarbonate Ringer solution in a Warburg respiration apparatus were not easily affected by radium, and that the respiration was much more sensitive. It is not possible to compare the actual doses given by Crabtree with the ones used in the experiments just described, because Crabtree used mixed  $\gamma$ - and hard  $\beta$ -radiations. The exact amount of  $\beta$ -radiation reaching the tissue cannot be calculated without the thickness of the glass vessels, the depth of fluid intervening, and so on, being known, and  $\beta$ -radiation is known to be far more biologically potent than  $\gamma$ -radiation. Nevertheless, some comparisons of my own work and Crabtree's are probably worth making.

It is notable that in Crabtree's experiments a considerable drop in respiration caused by exposure to radium did not lead to an increase in aerobic glycolysis, although (judging by his figures for anaerobic glycolysis) the glycolytic mechanism was not impaired to nearly the same extent as the respiratory mechanism. This might be explained on the idea put forward by Laser [1934] that the small

amount of respiratory activity remaining may be just that part of the cell respiration which is responsible for suppressing aerobic glycolysis.

On the other hand, it is possible that after irradiation, when the respiration is much lowered, there is also a much smaller aerobic breakdown of glucose. This would be disclosed by estimating the amount of glucose disappearing instead of estimating only the amount of acid appearing. If it should prove to be the correct explanation of Crabtree's figures, his results and mine would be mutually confirmatory, since I also find a decreased breakdown of glucose under aerobic conditions after irradiation.

*Use of the tissue culture method.*

There are definite advantages and also definite disadvantages in using the tissue culture technique instead of the ordinary respiration technique for work of this sort.

For work of the type described in this paper it is obviously useful to have the tissues under conditions which are known to be suitable for prolonged life, to be able to observe the effects of irradiation or other treatment on the growth and outwandering of the cells and to be able to continue the experiment for some days after irradiation if necessary. It was important in these experiments, for instance, to observe the tissues for 34 hours after the 14 hours' irradiation was completed, and to see that the dose given had not been sufficient to curtail the cell movements or cause obvious microscopic changes in their appearance.

Against the use of the tissue culture method it must be said that probably metabolic reactions are not proceeding at their optimum speed, since the atmosphere is air and not oxygen and the cultures are not usually shaken, although it is possible to arrange to shake them at intervals [Laser, 1932], or at the end of the experiment for the purpose of measuring respiration or fermentation. It is well known from respiration experiments [Dixon, 1934] that the rate of respiration may be considerably affected by the rate of shaking, since this determines to some extent the speed at which oxygen diffuses into the tissues and the speed at which fresh substrate becomes available and metabolic products are removed from the near neighbourhood of the tissue.

From this point of view it would be of interest to repeat our former experiments in an atmosphere of oxygen, which would ensure a more rapid diffusion of this gas, but some workers are of the opinion that an atmosphere of oxygen inhibits growth in cultures. The condition of partial anaerobiosis which probably exists in parts of the cultures may not be abnormal for embryonic tissue, since low oxygen tensions are experienced by the foetus *in utero*. It does, however, make comparison of experiments done in tissue cultures with those done in a respiration apparatus very difficult.

The question of the retarding of metabolic reactions in the cultures on account of slow diffusion of oxygen and other necessary substances is mentioned here because it may limit the detectable effects of irradiation. For instance, it is possible that if urea and ammonia formation were proceeding at the greatest possible speed, it might be found that irradiation with  $\gamma$ -rays did produce an inhibition, whereas in our experiments no inhibition was found. The same considerations apply to the experiments on arginine breakdown described in this paper. There is some evidence that these considerations apply less than might be expected in cultures where active outwandering is going on, as in our "growing cultures". No doubt the actual movements of the cells and the fact that they spread themselves over a considerable area and in a very thin layer, make the availability of oxygen and substrates greater than in inert cultures, and this may partly account for the considerable differences in metabolic activity we have

always found between growing and non-growing cultures [Holmes and Watchorn, 1927; Watchorn and Holmes, 1927].

Some attempts were made to avoid these difficulties by measuring the respiration of the cultures transferred to a respiration apparatus after the completion of the 14 hours' irradiation from the 300 mm. plaque and also after irradiation with radon. After 14 hours the respiration of both the control and the irradiated cultures was low, but that of the irradiated cultures was not consistently lower. Sometimes the irradiation reduced the respiration by about 50 % and sometimes it had no effect. These experiments were soon discontinued, but later experience suggests that if the irradiation were carried out at room temperature far larger doses could be given without the oxygen uptake of control tissue falling off seriously, and no doubt more consistent results could then be obtained.

There is a definite suggestion that the cultured tissues are less sensitive to irradiation than the tissues in glucose-bicarbonate Ringer's solution. It is not possible to draw this conclusion with certainty, however, since the amount of  $\beta$ -radiation reaching the tissues in Crabtree's experiments is not known.

From the work of Crabtree [1932], Crabtree and Cramer [1934], Frik and Posener [1926] and from my own experiments it seemed plain that the effect of  $\gamma$ -radiation upon the respiratory systems, and particularly those connected with carbohydrate oxidation, should be studied further. It was suggested to me by Prof. Keilin that the lactic dehydrogenase system might prove to be particularly sensitive.

#### *Experiments with lactic dehydrogenase.*

The usual cultures of embryo rat kidney tissue were exposed to the same dose of  $\gamma$ -radiation as that used for the earlier work (14 hours' exposure at a distance of 0.5 cm. to 300 mg. element contained in a platinum capsule 0.3 mm. thick) and at the end of the 14-hour period were put into vacuum tubes and tested for their dehydrogenase activity in the presence of lactate by the usual methylene blue technique.<sup>1</sup> On two occasions this was tried, and the irradiated culture showed no change of reduction time when compared with the control culture. The amount of tissue was small and the reduction very slow in both cases, and it was therefore decided not to use the culture method for these experiments. Instead, minced tissue was placed in small flat-bottomed tubes; the area of the bottom of the tubes was almost exactly the same as that of the top of the capsule containing the radium. The depth of tissue in the tubes was about 0.5 cm. and thus much greater than the depth of tissue in the cultures, and in order to secure a sufficiently large dose of  $\gamma$ -radiation throughout the depth of tissue, the tubes were placed directly upon the capsules and the time of exposure increased to 16 hours. The whole experiment was carried out at 37°. The control tubes were kept in the same incubator, but were screened with lead blocks.

It has been our usual practice to use rat embryos as nearly as possible at term, since the amount of kidney tissue available is otherwise too small. On one occasion the rat was killed about 5 days before term, and it was therefore necessary to use brain tissue instead of kidney for the irradiation experiments. On this occasion it was found that the reduction time was very much prolonged by the irradiation. This suggested either that the lactic dehydrogenase system of brain tissue was more sensitive than that of kidney, or that the younger embryo tissue was more sensitive than that of embryos at term.

<sup>1</sup> Experiments carried out with and without added lactate suggest that a considerable proportion of the dehydrogenase activity of the tissue is, in fact, due to lactic dehydrogenase. Some inaccuracy is no doubt involved in speaking throughout this paper of "lactic dehydrogenase" when other dehydrogenases may also be concerned.

To test this point, the brain tissue of embryos at term was next exposed to the radiation, and it was again found that the reduction time was unaltered. It therefore appeared that the sensitivity of the lactic dehydrogenase system was considerably greater in the embryos 5 days before term than in those at term. This result was repeated six or seven times at each age and was confirmed.

The range of embryonic ages at which it is possible to carry out the experiments is limited by the need for a reasonable amount of tissue, and whilst it so happens that, with the breed of rats in use in this laboratory, there is a sharp change in sensitivity during the last 5 days of gestation, it is not likely that it will occur at just this stage in all breeds. In fact, on the two or three occasions when we have used albino or brown and white rats instead of the black and whites, the tissue of the embryos at term has proved to be still sensitive (in respect of its lactic dehydrogenase system) to the  $\gamma$ -radiation.

Brain tissue from the chick embryo is far more satisfactory from the point of view of affording a wider range of ages. The experiments were repeated once with 8- and once with 18-day eggs and it was found once more that the reduction time of the 18-day tissue was unaltered, whilst that of the 8-day tissue was increased 100%.

The examples given in the first part of Table I are quite typical, and it will be noticed that the reduction time of the young embryo tissue was usually doubled after irradiation. The large difference in reduction times between the various experiments is due to the use of different amounts of tissue.

Table I.

Reduction time in min.

Control	Irradiated	Increase % Experiments at 37°.	Tissue
40	50	25	Rat at term
120	150	25	Rat at term
25	23	0	18-day chick embryo
150	>480	>300	Young rat embryo
30	60	100	Young rat embryo
30	60	100	8-day chick embryo
Experiments at room temperature.			
13	17	30	Rat at term
15	17	13	Rat at term
*10	*19	*90	*Rat at term
11½	14	23	18-day chick embryo
23½	50	117	8-day chick embryo
23	38	65	Young rat embryo
8	16	100	Young rat embryo
5	7½	50	Adult rat

It was found that when the irradiation was carried out at 37° the reduction times of both the irradiated and the control tissues were enormously larger than that of fresh tissue, being half an hour to an hour instead of about 3 min. Tissues kept overnight at room temperature did not lose their reducing power to any great extent, and it was therefore decided to repeat the irradiation experiments at room temperature in case the condition of the tissue and of the dehydrogenase systems was a determining factor in their sensitivity to  $\gamma$ -rays. The results are given in the lower half of Table I; the amounts of tissue taken were smaller and the amounts of dye larger than in the first experiments, so that the difference in dehydrogenase activities between the tissues kept at 37° and those kept at room temperature is greater than appears from the Table.

The number of experiments done at room temperature was not large enough (they are all included in the Table) to allow of any certainty, but it did not appear that the conditions greatly altered the sensitivity of the dehydrogenase systems to radium. The lactic dehydrogenase of the young tissue was still more easily affected than that of the tissue from older embryos, although in one case (marked \*) the reduction time of the tissue from an embryo at term was doubled by the exposure to  $\gamma$ -radiation. On one occasion only was the tissue from a young chick egg found to be insensitive to  $\gamma$ -rays at room temperature; this example is not included in the Table, as there was a definite possibility that the tissue was damaged by accidental overheating.

It is of course obvious that before this difference in response to  $\gamma$ -radiation between young and old embryo tissues can be regarded as definitely proved the experiments must be repeated a great many times. Unfortunately that is not possible under the present conditions of work. Experiments with radium have always suggested considerable variations in sensitivity between individual tissues and no doubt some cases would be found where the lactic dehydrogenase of young tissue was less sensitive and that of older tissue more sensitive than usual. On the other hand, in view of the fact that some workers have considered that embryo tissue is more easily killed by irradiation than adult tissue, it would be well worth while establishing definite differences of this sort in their metabolic response to irradiation.

Of much greater immediate interest is the question of what part of the lactic dehydrogenase system—the enzyme itself or the co-enzyme—is destroyed by  $\gamma$ -rays. One or two preliminary experiments have suggested that it is the co-enzyme that is destroyed in the sensitive tissues. The addition of co-zy-mase to the tissues increased the rate of methylene blue reduction of the irradiated tissue up to the normal level. It is hoped to investigate this point further in the future.

#### *Experiments with arginase.*

In view of the observation that urea and ammonia production in cultures was not altered by the dose of  $\gamma$ -rays given it seemed worth determining whether arginase, which is in all probability one of the enzymes concerned in the urea formation, was similarly unaffected. Arginine was added to the cultures at the beginning of the experiment, and the total urea and ammonia estimated at the end of 48 hours. Part of the urea and ammonia found would of course be due to the ordinary metabolic processes of the cell, but the figures obtained were greatly in excess of those found in the absence of added arginine, and a large proportion of the total urea +  $\text{NH}_3$ -nitrogen found must be accounted for as urea formed from arginine. This is especially the case in Exps. 161, 162 and 164, where glucose

Table II. *Arginase experiments.*

Total urea- and ammonia-nitrogen in cultures in mg.				
Exp. no.	Control at 0°	Control culture	Irradiated culture	Difference between irradiated and control
159	0.097	0.151	0.204	+ 0.053
160	0.073	0.184	0.192	No difference
161	0.068	0.180	0.180	No difference
162	0.071	0.240	0.196	- 0.044
164	0.090	0.190	0.213	+ 0.023
	14 hours' incubation	3 days	3 days	
189	0.110	0.171	0.171	No difference

was present in the medium, and the ordinary formation of urea and ammonia would therefore have been very small [Watchorn and Holmes, 1927].

It can be seen that the irradiation had no effect on the breakdown of arginine. It is worth mentioning that on two occasions the glucose was also estimated and, although the amounts broken down were too small for great accuracy, it appeared that glucose breakdown was as usual inhibited by the irradiation whilst the arginine breakdown remained unaltered (Exps. 161 and 164).

In order to make certain that any impairment of arginase activity would become obvious in the experimental conditions, Exp. 189 was undertaken. On this occasion the concentration of arginine was high (400 mg. arginine hydrochloride per 100 ml. Ringer's solution, i.e. 8 mg. in each culture), the medium was stirred at the end of 14 hours, and the estimation on one culture was made at the end of 14 hours, the others being left for 48 hours as usual. It was hoped by this means to secure sufficient access of the substrate to the arginase and also to demonstrate that arginine breakdown was still continuing after the full dose of irradiation had been received, as in fact proved to be the case.

These cultures were made in the ordinary way in 2 ml. of embryo extract in pyrex flasks, the embryo rat kidney tissue being supported on cotton-wool strands.

In connection with the effect of irradiation on nitrogen metabolism, mention should be made of Lawrie's [1935] paper on the effects of  $\gamma$ -rays on the ammonia production of *Bodo caudatus*, as this illustrates very well the fact that completely different effects can be obtained by varying the dose of  $\gamma$ -rays.

#### SUMMARY.

1. The advantages and disadvantages of the tissue culture method for studying the effect of irradiation on tissue metabolism are discussed.
2. Experiments are described showing that the lactic dehydrogenase system in the tissue of young embryos is more easily damaged by  $\gamma$ -rays than that in the tissue of older embryos.
3. Reference is made to preliminary experiments which suggest that the part of the dehydrogenase system injured by the  $\gamma$ -rays may be the co-enzyme.
4. Experiments are described showing that the arginase activity of a tissue culture is not impaired by a dose of  $\gamma$ -rays which is sufficient to cause considerable inhibition of glucose breakdown.

I have to thank the Medical Research Council and the British Empire Cancer Campaign for personal grants given while this work was in progress.

# CCLXXI. INORGANIC CONSTITUENTS OF THE CEREBROSPINAL FLUID.

## VI. SULPHUR.

BY ELSIE WATCHORN AND ROBERT ALEXANDER McCANCE.

*(From the Biochemical Laboratory, Cambridge and King's College  
Hospital, London.)*

*(Received August 15th, 1935.)*

A NUMBER of papers have appeared in recent years on the relationship between the constituents of the cerebrospinal fluid and the blood serum. Calcium, magnesium, potassium and inorganic phosphorus have all been studied more or less extensively, but inorganic sulphur, as Flexner [1934] has pointed out, has been largely neglected. Mestrezat [1912] was probably the first to estimate the sulphur of cerebrospinal fluid, but his values were probably much too high (49-90 mg.  $\text{SO}_3$  per 100 ml.), and he did no parallel investigation of the serum. Meyer-Bisch [1922] stated that the cerebrospinal fluid sulphur was higher than that of the serum, both normally and in two pathological non-meningeal cases. The serum values ranged from 12 to 22 mg.  $\text{H}_2\text{SO}_4$  per 100 ml. and the corresponding cerebrospinal fluid values were 20-98 mg.  $\text{H}_2\text{SO}_4$  per 100 ml. These figures for serum were later shown to be too high [Heubner and Meyer-Bisch, 1926] but no correction was made for the cerebrospinal fluid. Haurowitz [1923] found an average value of 1.1 mg. S per 100 ml. for the total sulphur of the cerebrospinal fluid (*i.e.* inorganic sulphur + protein sulphur) of which he calculated that approximately four-fifths was inorganic. He compared this with the normal serum values given by Heubner and Meyer-Bisch [1921] and concluded that sulphur did not enter the cerebrospinal fluid solely by ultrafiltration. As stated above Heubner and Meyer-Bisch [1926] later pointed out that the figures taken for serum at that time were too high, and actually the value found by Haurowitz for the cerebrospinal fluid was about equal to that of normal serum which various workers have now established to be 0.5-1.5 mg. of S per 100 ml. The results of Haurowitz might therefore be taken to support the origin of cerebrospinal fluid by ultrafiltration.

Very little work also has been carried out on the partition of sulphur between serum and ocular fluids. Heubner and Meyer-Bisch [1921] concluded that ocular fluids contained less sulphur than serum ultrafiltrates, and Tron [1928] concluded similarly that ocular fluid contains less inorganic sulphur than the serum. Duke-Elder [1927, 1, 2], however, found rather more sulphur in the aqueous humour than in serum and considered that the aqueous humour represented a serum dialysate or ultrafiltrate. There is therefore experimental disagreement as to whether the aqueous humour should be regarded as obtaining its sulphur by secretion or by ultrafiltration, and the cerebrospinal fluid equilibrium clearly requires further investigation.

### METHODS AND TECHNIQUE.

Human material only has been studied and all of it has been obtained from in- and out-patients of King's College Hospital. The blood was taken from an antecubital vein with the minimum amount of constriction, and the fluid was

withdrawn immediately afterwards. Cerebrospinal fluid was obtained by lumbar puncture. Ventricular fluid was taken by ventricular puncture under gas and oxygen anaesthesia, but otherwise no anaesthetics have been employed. The samples were not taken at any particular time of the day or in any definite relation to a meal. The blood was allowed to clot at room temperature and the serum was separated as soon as the clot had retracted. Serum and fluid were then transferred to small bottles and dispatched to Cambridge for analysis [McCance and Watchorn, 1931]. A description of the membranes, ultrafiltration technique and other points of detail may be found in previous papers by the authors [Watchorn and McCance, 1932; 1933; McCance and Watchorn, 1932].

The method used for estimating inorganic sulphur was essentially that of Cuthbertson and Tompsett [1931], but some modifications were introduced. The proteins were precipitated by adding an equal volume of 20% trichloroacetic acid to the undiluted serum [Hubbard, 1930; Cope, 1931]. The precipitate was filtered through acid-washed filter-papers. The commercial acid-washed papers were found to contain appreciable amounts of sulphur and were rewashed with dilute acetic acid. Considerable difficulty was encountered in the washing of the benzidine sulphate precipitate. No means of removing the supernatant wash-fluid could be devised which did not tend to disturb the precipitate and to lead to a loss which, though unimportant in relation to large precipitates, formed a considerable percentage error in the case of the small precipitates. The difficulty was finally fairly satisfactorily overcome by washing with a mixture of acetone and water (80 ml. of acetone made up to 100 ml. with sulphur-free distilled water). This modification has been followed also by Pirie [1934, 2]. The suggestion of Cope [1931] that the centrifuge-tube should be drained over filter-paper moistened with acetone was found to be useful, as it prevented evaporation of acetone before drainage was complete and consequent deposition of benzidine on the sides of the tube. The mouth of the tube should be wiped dry with filter-paper before turning the tube into the upright position. Alterations were also introduced into the colorimetric part of the determination, chiefly in order to avoid the awkward measurements of Cuthbertson and Tompsett. 1 ml. of 0.1% sodium nitrite was added to the benzidine sulphate dissolved in *N* HCl, followed by 5 ml. of alkaline thymol solution (0.5% thymol in 10% NaOH). As stated by Pirie [1934, 1, 2] the additional 15% NaOH is unnecessary and it also retards the colour production. When very small amounts of sulphur were being estimated 3 ml. of the alkaline thymol were used to obtain a smaller volume and consequently a deeper colour. With all possible precautions the method did not always give good duplicates, and this was particularly so when the amounts of sulphur were small.

The range of very low values for normal serum inorganic sulphur given by Cuthbertson and Tompsett [1931] have not been confirmed. The few normals examined fell within the range given by other workers (Cope, 1931; Denis, 1921; Loeb and Benedict, 1927; Udaonda *et al.*, 1933), *i.e.* 0.5–1.5 mg. of S per 100 ml.

Table I. *Serum compared with plasma.*

Serum mg. S per 100 ml.	Plasma mg. S per 100 ml.
3.2	4.3
19.2	19.5
2.2	2.1
0.7	0.6
9.3	10.0
1.4	1.4

Before starting the series of experiments described below, a number of comparisons were made between serum, obtained as above mentioned, and plasma. The latter was obtained by centrifuging the blood immediately on withdrawal, minimum amounts of pure sodium oxalate being used to prevent coagulation. Table I shows that it is immaterial whether serum or plasma is used for the estimation of inorganic sulphur and that no breakdown of organic sulphur takes place during the separation of the serum.

## RESULTS.

In Table II are given comparisons of the inorganic sulphur in serum, serum ultrafiltrates and cerebrospinal (lumbar puncture) fluid. The cases have been arranged into three groups: Group (a) *General neurological diseases*. In these

the inorganic sulphur of the serum averaged 2 mg. of S. per 100 ml. and all of it was ultrafiltrable. The cerebrospinal fluid however averaged only 0.6 mg. S per 100 ml., which is between one-third and one-fourth of the serum or ultrafiltrable value. The range of cerebrospinal fluid values has been found to be wider than that shown by other inorganic constituents [McCance and Watchorn, 1931; Watchorn and McCance, 1932; 1933]. This may be due partly to a larger experimental error in the method of analysis, and this may also explain the greater fluctuations in individual ultrafiltrate figures compared with those for the corresponding sera. The range of serum values in these miscellaneous cases corresponds with those found by others [Loeb and Benedict, 1927; Udaonda *et al.*, 1933; Wakefield, 1929].

Group (b) *Chronic interstitial nephritis*. It has already been shown many times [Haurowitz, 1923; Loeb and Benedict, 1927; Meyer-Bisch, 1924; Kahn and Postmontier, 1925; Denis *et al.*, 1928; Wakefield and Power, 1931] that the inorganic sulphur of the serum is increased in renal insufficiency. The whole of it, however, appears to be ultrafiltrable. The cerebrospinal fluid sulphur, though higher than in Group (a), was still only a quarter that of the serum.

Table III. *Inorganic sulphur in sera and non-purulent effusions.*

"	"	1.3	—	1.1
	Average	2.4	—	2.8

Group (c) *Meningitic cases*. The inorganic sulphur of the serum tended on the whole to be lower and that of the cerebrospinal fluid higher than in group (a) but exceptions have been found in both directions. The cerebrospinal fluid sulphur was never actually higher than the serum level but the average was only slightly lower. Meyer-Bisch [1924] stated that in tubercular meningitis the cerebrospinal fluid sulphur was generally higher than normal.

A number of simple effusions of various types were compared with serum (Tables III). On an average the fluids contained slightly more inorganic sulphur than the sera and in this respect resemble ultrafiltrates. Heubner and Meyer-Bisch [1926] stated that only two-thirds of the serum inorganic sulphur was found in pleural and ascitic fluids, but these authors did not examine serum and fluid from the same patient.

A short series of sulphur determinations was made in ventricular fluids (Table II). In one case the corresponding fluid obtained by lumbar puncture was withdrawn within a few minutes of the ventricular puncture. The sulphur contents of these two were identical, and the average of the ventricular fluids was exactly the same as that of the lumbar fluids in group (a) of Table II.

## DISCUSSION.

The present results support those of Hayman and Johnston [1932] in showing that the whole of the serum inorganic sulphur is ultrafiltrable. In this connection it is interesting to note that both Meyer-Bisch [1924] and de Boer [1917] determined the sulphur in serum ultrafiltrates as their method of measuring the inorganic sulphur content of the serum. The amount of sulphur found in effusions from various sites and with various pathological causation also resembles the amount found in serum ultrafiltrates. It is reasonable therefore to suggest that inorganic sulphur reaches these fluids by ultrafiltration. Gilligan *et al.* [1934] consider that this is true also of all other ions. A study of Table II makes it evident that the sulphur in cerebrospinal fluid cannot be explained on the same basis. Since moreover ventricular fluids contain the same amounts as the lumbar puncture fluid there can be no suggestion that the amounts of sulphur in the latter are due to changes in this fluid during its passage from the ventricles. One must assume therefore that as regards sulphur the cerebrospinal fluid cannot be regarded as an ultrafiltrate. This is in keeping with what has been found for other constituents, both organic and inorganic [Flexner, 1934; McCance and Watchorn, 1931; 1932; 1934; Watchorn and McCance, 1932; 1933; Gilligan *et al.*, 1934; Walker, 1933], but owing to the extensive variations in serum inorganic sulphur which are encountered pathologically the sulphur ion provides new and valuable evidence. In this small series it is to be noted that when the serum inorganic sulphur rises very greatly, as in uraemia, that of the cerebrospinal fluid also rises and the normal ratio between the two tends to be maintained. This is being further investigated. In many cases of meningitis the "normal" fluid/serum ratio seems to be lost and the relationship approaches that of the ultrafiltrate/serum. It is impossible to say from this small series whether a fall in the serum value plays a significant part in this, but the problem will be further studied. The rise in the cerebrospinal fluid sulphur is probably more significant. The change is to be compared with the rise in cerebrospinal fluid phosphorus [Cohen, 1923-24] and the fall in magnesium [McCance and Watchorn, 1932] which accompanies meningitis. The fall in chlorides may or may not be comparable, but the evidence is accumulating that in meningitis (especially tuberculous meningitis) changes take place in the secretory activity of the choroid plexus which are reflected by changes in a number of the chemical constituents of the cerebrospinal fluid.

## SUMMARY.

1. The serum inorganic sulphur in non-nephritic patients lay between 1 and 4 mg. per 100 ml. In chronic interstitial nephritis values up to 35 mg. per 100 ml. were found.
2. The whole of the serum inorganic sulphur was ultrafiltrable.

3. The inorganic sulphur in ventricular and cerebrospinal (lumbar puncture) fluids was approximately one-quarter to one-third of the serum value. These fluids, therefore, do not represent serum ultrafiltrates.

4. In tuberculous meningitis the cerebrospinal fluid sulphur tended to rise and to approach the serum value.

5. The inorganic sulphur in pathological effusions could be accounted for satisfactorily by supposing that such fluids had been formed by ultrafiltration.

The authors wish to thank all those who have helped them to obtain material for this investigation. One of them (E. W.) is indebted to the Medical Research Council for a personal grant.

# CCLXXII. STUDIES IN THE METABOLISM OF PROTOZOA.

## II. SOME BIOCHEMICAL REACTIONS OCCURRING IN THE PRESENCE OF THE WASHED CELLS OF *GLAUCOMA PYRIFORMIS*.

By NORMAN RISBOROUGH LAWRIE.<sup>1</sup>

*From the Bonnett Memorial Laboratory, Addenbrooke's Hospital, Cambridge.*

*(Received August 1st, 1935.)*

It is the purpose of the present communication to draw attention to the biochemical activity exhibited in a simplified environment by the protozoon *Glaucoma pyriformis*. The valuable data obtained by the investigation of the biochemical properties of suspensions of washed bacteria suggested the extension of such methods to the study of the protozoa. Such work is highly desirable on account of the biological and medical importance of this phylum. The remarkable environmental changes undergone by certain parasitic species of protozoa in the course of their life-cycle may be expected to furnish instructive instances of biochemical adaptations. A suitably chosen protozoal culture offers material for biochemical study which possesses a degree of homogeneity and freedom from specialisation of cellular function greater than that which obtains in the tissues of the higher animals. The complexity of the media required for the cultivation of the protozoa has hitherto rendered such work almost impossible. Within recent years, however, progress in the cultivation of protozoa in bacteriologically sterile, and even non-particulate, media, has rendered a limited number of species amenable to biochemical studies of this type [Lwoff, 1932].

Little biochemical work appears to have been carried out upon suspensions of protozoa separated from the medium upon which they have been grown. Hartog and Dixon [1893] collected specimens of the very large multinucleated protozoon *Pelomyxa palustris*. After treatment with alcohol, the protozoa were removed individually from contaminating material by means of a mounted needle, dried over sulphuric acid and pulverised. The resulting powder was moistened with alcohol and extracted with water. This extract readily hydrolysed starch to crythrodextrin (though the subsequent formation of reducing sugars was very slow) and dissolved fibrin in the presence of dilute acids. No change was perceptible when milk preserved with thymol was treated with the extract. Mouton [1902] described the preparation of a culture on gelatin containing one species of amoeba and one species of bacterium. A proteolytic enzyme in aqueous solution was obtained from these cultures. It was shown by control experiments that this enzyme could not have been extracted from the bacterial component of the cultures (*B. coli communis*). This protease, which was most active in slightly alkaline media, digested gelatin and fibrin but had little action upon coagulated egg albumin. Mesnil and Mouton [1903] cultivated *Paramoecium aurelia* in the presence of bacteria. The paramoecia, concentrated electrically, were able to liquefy gelatin. The reaction proceeded most rapidly in media which were neutral to litmus. Fenyvessy and Reiner [1928] measured the

<sup>1</sup> Beit Memorial Research Fellow.

respiration of trypanosomes washed by centrifuging and suspended in a solution of glucose and salts. Reiner and Smythe [1933-34] obtained suspensions of *Trypanosoma equiperdum* by fractional centrifuging of the blood of infected rats. Such suspensions, which contained very few red blood corpuscles, were shown to catalyse the breakdown of glucose into glycerol and pyruvic acid and the oxidation of glycerol to pyruvic acid.

The strain of *G. pyriformis* used in the present experiments was very kindly given to me by Dr Muriel Robertson, of the Lister Institute, London. It was cultivated upon a simple medium consisting of 1% "Difco" peptone and 0.4% of a simple salt mixture, dissolved in distilled water and sterilised by autoclaving. The bacteriological sterility of the cultures was tested from time to time by attempted aerobic subculture at 35° in glucose broth. The cultures used in the experiments described below were all bacteriologically sterile as judged by this test. Treatment of the culture with sterile quinamil (B.D.H.) solution was carried out as a precaution against bacterial contamination during the inoculations of numerous subcultures.

The cultures were allowed to grow for about 7 days. The protozoa were then separated from the culture fluid by centrifuging and twice washed by resuspension in 20 ml. of distilled water and centrifuging. The washed protozoa were then suspended in a suitably buffered solution, or in water, according to the requirements of the experiment in hand. The numbers of protozoa in the cultures were counted by means of the Fuchs-Rosenthal counting chamber. A considerable number of protozoa became disintegrated during these processes, so that the final reacting system contained not only intact cells, but also the insoluble products of cytolysis of some protozoa and any insoluble materials derived from either protozoa or medium during the development of the culture.

In order to test the suitability of these suspensions for biochemical study they have been examined for the presence of a representative series of enzyme systems, with the results described below.

#### PROTEASE.

Digestion mixtures containing suspension of *Glaucoma pyriformis*, buffer, protein solution and chloroform were set up in test-tubes and incubated, usually for 24 hours. Chloroform was used to cytolysed the protozoa and to inhibit bacterial growth and for these purposes was considered to be better than toluene.

The extent to which proteolysis had occurred was measured by precipitation of the undigested protein with trichloroacetic acid, filtration and estimation of the total nitrogen in a portion of the filtrate. For this estimation the method of incineration of Wong [1923] was found to be suitable, followed by distillation of the ammonia into standard acid and back-titration with carbon dioxide-free  $N/500$  NaOH. This procedure permitted estimation of the non-protein-nitrogen to the nearest 1 mg. per 100 ml. of digest.

Boiled suspensions of *G. pyriformis* had no measurable proteolytic action on caseinogen. Autolysis at  $p_H$  6.0 yielded only a small and variable increase in the non-protein-nitrogen of the digest, ranging from nil to 2 mg. per 100 ml. The following experiments are typical of the results obtained.

Exp. 1. Each digestion tube contained:

2% sodium caseinogenate	...	1 ml.
M/20 buffer	... ..	1 ml.
<i>Glaucoma</i> suspension	... ..	0.5 ml.
Chloroform	... ..	0.5 ml.

The population of the culture was such that if no loss of cells had occurred during centrifuging the digests would have contained  $15.6 \times 10^6$  cells per 100 ml. The increase in non-protein-nitrogen after 24 hours' incubation at  $30^\circ$  is shown in Table I.

Table I. *Proteolysis of caseinogen in acid media.*

$p_H$	Increase in non-protein-nitrogen mg./100 ml.
2.2 phthalate buffer	5
4.0 " "	10
6.0 " "	16
6.0 phosphate "	21
7.0 " "	15
6.0 autolysis in phthalate buffer	2

The caseinogen was mostly out of solution in the tubes at  $p_H$  4.0 and 2.2.

Exp. 2. A set of digestions was prepared similar to that used in Exp. 1. There was the equivalent of  $32 \times 10^6$  cells present per 100 ml. of the digest. The results of 24 hours' incubation at  $30^\circ$  are shown in Table II.

Table II. *Proteolysis of caseinogen in alkaline media.*

$p_H$	Increase in non-protein-nitrogen mg./100 ml.
8.4 borate buffer	10
8.6 " "	9
8.8 " "	9
9.0 " "	8
9.2 " "	8
9.4 " "	7
9.6 " "	7

From these and similar experiments it was concluded that the optimum  $p_H$  for the proteolysis of caseinogen by a suspension of *G. pyriformis* was near 6.

In other experiments the sodium caseinogenate was replaced by egg albumin (B.D.H.). Very little proteolysis occurred, however, either with untreated or with heat-coagulated egg albumin. This difference in the ability of the *Glaucoma* suspension to proteolyse caseinogen and egg albumin respectively is brought out by the following experiment.

Exp. 3. To each of three test-tubes were added:

<i>M/20</i> phosphate buffer at $p_H$ 6.0	...	...	1.75 ml.
<i>Glaucoma</i> suspension	...	...	0.50 ml.
Chloroform	...	...	0.50 ml.

Table III. *Proteolysis of caseinogen and egg albumin compared.*

Tube	Increase in non-protein-nitrogen mg./100 ml.
A	3
B	16
C	2
	Increase in non-protein-nitrogen due to proteolysis of added substrate
A	1
B	14

To tube A were added 2.25 ml. of 0.5 % egg albumin, to tube B 2.25 ml. of 0.5 % sodium caseinogenate and to tube C 2.25 ml. of distilled water. These tubes contained the equivalent of  $31 \times 10^6$  cells per 100 ml. The non-protein-nitrogen was estimated in each tube and they were then incubated for 24 hours. At the end of that period the non-protein-nitrogen was again estimated, with the results shown in Table III.

Thus it is clear that a suspension of *Glaucoma pyriformis*, saturated with chloroform, can carry out proteolysis at  $p_H$  values ranging from 2.2 to 9.6.

#### DIASTASE.

The presence of a diastase in suspensions of *G. pyriformis* is readily demonstrable. The following typical experiment shows this property. 11 ml. of a suspension of *G. pyriformis* in *M*/20 phosphate buffer at  $p_H$  7.0 were prepared and found to contain  $34 \times 10^6$  cells per 100 ml. 5 ml. of this suspension were measured into two monax test-tubes, A and B. Tube A was placed in a boiling water-bath for 15 min. and then cooled. Both tubes then received 0.25 ml. of 1 % starch in 5 % sodium chloride solution and a few drops of toluene. They were then incubated at 37°. About 0.5 ml. was removed from each tube at intervals and tested for the presence of starch by means of a dilute iodine solution. The results obtained are shown in Table IV.

Table IV. *Diastatic action of G. pyriformis.*

	Result of iodine test for starch	
	Tube A	Tube B
At start of incubation	Deep blue	Deep blue
After 3 hours' incubation	"	Faint red
" 4½ "	"	"

In other experiments of a similar type but without the addition of toluene no colour was developed with iodine after 4 hours' incubation. These digests did not reduce Fehling's solution.

#### PEROXIDASE.

Preliminary experiments with the suspension of *G. pyriformis* showed that it exhibited strong peroxidase-like activity in the presence of 50 % acetic acid.

In order to determine whether a true peroxidase enzyme were present, or whether the effect were due to catalysis by haematin compounds, the following comparative experiments were carried out.

A suspension in water containing  $52 \times 10^6$  protozoal cells per 100 ml. was prepared. Scrapings from horse-radish were ground with distilled water and the extract decanted off to provide a typical plant peroxidase system. A very dilute suspension of human blood in distilled water was used to provide a "pseudo-peroxidase" system. These three preparations were compared in the following series of experiments.

In Exp. I, 15 mg. of benzidine, 1 ml. of *M*/20 phosphate buffer at  $p_H$  7.0, 0.1 ml. of 20 vol. hydrogen peroxide and 0.25 ml. of enzyme preparation were mixed in a porcelain crucible. Exp. II was set up in the same way as Exp. I, except that the phosphate buffer was replaced by 50 % acetic acid. Exps. III and IV were repetitions of I and II respectively, in which the fresh catalytic systems were replaced by the same systems after they had been heated for 1½ hours in the boiling water-bath. The results of these experiments are summarised in Table V.

Table V. *The peroxidase action of a suspension of G. pyriformis.*

The sign + indicates a positive colour reaction and the sign - that no coloured product was formed.

Exp. no.	Source of catalyst		
	Horse-radish	Blood	<i>Glaucoma</i>
I } Unheated catalysts	+	-	-
II } Unheated catalysts	+	+	+
III } Heated catalysts	-	-	-
IV } Heated catalysts	-	+	-

Exps. III and IV show definitely that the peroxidase in *Glaucoma* is thermolabile, and in this property differs from the peroxidase-like system of certain bacteria [Callow, 1926] and from the peroxidase-like action of haematin compounds.

When benzidine is used as the indicator of peroxidase action the activity of the peroxidase in the suspension of *Glaucoma* is greatest in acid preparations. In later experiments, using *p*-phenylenediamine, this peroxidase brought about oxidation at  $p_H$  7.0,  $p_H$  2.2, or in the presence of approximately 50% acetic acid.

#### DEHYDROGENASE.

Suspensions of *Glaucoma* were tested for dehydrogenase activity by means of the Thunberg tube technique. Small tubes of about 5 ml. capacity were used, and contained:

Suspension	...	...	...	...	0.5 ml.
Buffered methylene blue solution	...	...	...	...	0.5 ml.
Substrate	...	...	...	...	0.5 ml.

There was a final concentration of methylene blue in the Thunberg tube of 0.005% and of phosphate buffer at  $p_H$  7.0 of *M*/60. The tubes were evacuated on the water-pump and placed in a water-bath at 37°. The time taken for complete decoloration was observed. It was found that the washed protozoal cells reduced the methylene blue rapidly in the absence of any added substrate. The rate of reduction of methylene blue was however accelerated by the addition of succinate to the system. Aeration, and starvation of the organisms in sterile distilled water, did not increase the acceleration of the rate of reduction of methylene blue caused by the addition of succinate. The results of a typical experiment are given in Table VI.

Table VI. *Reduction of methylene blue in the presence of G. pyriformis.*

The activity of the reducing system is expressed as 100/reduction time in minutes.

Substance added	Time required for complete reduction of methylene blue min.	Activity of reducing system	Increase in activity due to added substance
Water	28	3.6	—
<i>M</i> /15 sodium succinate	22½	4.4	25%
<i>M</i> /15 glucose	28	3.6	Nil

Glucose and sodium succinate in the presence of boiled protozoal suspension did not reduce methylene blue. In addition to glucose, negative results were obtained with fructose, lactose, sodium formate and hypoxanthine. The increase in the activity of the reducing system caused by the addition of succinate varied

in different experiments from 25 to 43 %. It is concluded that succinic dehydrogenase is present in the cells.

Attempts to remove substrate from the cells by the methods of washing and aeration usually successful with bacteria only resulted in loss of activity of the enzyme. Treatment of the suspensions with toluene or phenol along the lines of the experiments of Quastel and Wooldridge [1927] upon the dehydrogenases of *B. coli* resulted in complete loss of dehydrogenase activity. The protozoon *G. pyriformis* differs from many bacteria and many animal tissues in the tenacity with which it retains substances capable of reducing methylene blue. Its behaviour in this respect resembles that of *Bacterium faecalis alkaligenes*, described by Quastel and Wooldridge [1925].

#### THE PRESENCE OF GLUTATHIONE IN *G. PYRIFORMIS*.

The nitroprusside test for the organic sulphhydryl group was applied to suspensions of *G. pyriformis* after the manner adopted by Callow and Robinson [1925] in the case of certain bacteria. 300 ml. of a well-grown culture were centrifuged and the cells twice washed with 40 ml. of distilled water. The deposit of protozoa was then transferred to a small weighed dish and dried *in vacuo* over sulphuric acid to constant weight. 74 mg. of dry material were obtained. There were  $34 \times 10^6$  cells in the material taken. 2 ml. of a saturated aqueous solution of ammonium sulphate were added to this dry material, well stirred and allowed to stand for 15 min. A few mg. of potassium cyanide were then added and the material filtered through a small plug of absorbent wool. To this filtrate 0.2 ml. of a freshly prepared 1 % aqueous solution of sodium nitroprusside and 0.2 ml. of ammonia solution (1 vol. of ammonia solution of sp. gr. 0.88 diluted to 5 vol. with distilled water) were added. A strongly positive reaction was given immediately. Subsequent similar experiments in which the addition of potassium cyanide was omitted also gave a positive reaction. 16.5 mg. of the dried protozoa were extracted with 2 ml. of 5 % trichloroacetic acid and tested for cystine by means of Sullivan's test. No cystine (or cysteine) was found to be present. It is concluded from these experiments that the cells of *G. pyriformis* contain glutathione in the reduced form.

#### SUMMARY.

The presence of a protease, diastase, dehydrogenase and peroxidase has been demonstrated in the protozoon *Glaucoma pyriformis*. The presence of glutathione in these organisms is inferred from the results of applying the nitroprusside test for the organic —SH group and Sullivan's test for cystine and cysteine to extracts of the dried cells.

I am deeply indebted to Sir F. G. Hopkins for his interest in this work.

# CCLXXIII. THE MECHANISM OF CATALASE INHIBITIONS.

By HERMANN BLASCHKO.

*From the Physiological Laboratory, Cambridge.*<sup>1</sup>

*(Received August 10th, 1935.)*

THE experiments recorded in this paper represent an introduction to a study of the effect of catalase inhibition on tissue respiration. Before this problem could be approached, it was desirable to obtain information as to the mechanism of the inhibitory action of substances that are known to act more or less specifically on catalase. This paper deals mainly with the question as to whether the action of a given substance on the enzyme is reversible.

The two principal catalase inhibitors so far studied are cyanide and sulphide. These substances have not been included in the present work because (a) they exhibit such striking properties as inhibitors of cell respiration that they are not suitable for the final purpose of our investigation, and (b) it has already been proved that the action of both drugs is a reversible one. [Rona *et al.*, 1925. For full references see Euler, 1934.] The reversibility of these inhibitions can be demonstrated by bubbling air through solutions containing the poisoned enzyme. This method is obviously suitable only in the case of a volatile inhibitor. Another possible way of deciding whether an inhibition is reversible or not can only be used in heterogeneous systems: *e.g.* the reversibility of the cyanide inhibition of hydrogen peroxide decomposition by palladium black has been demonstrated by washing the catalyst and adding new substrate [Blaschko, 1926].

For the present work it was necessary to use a method that was applicable in the case of non-volatile substances acting in a homogeneous solution. The action of catalase was followed manometrically using the Warburg type of the simple Barcroft manometer. The reversibility of the inhibition was studied in specially made manometer flasks in which the concentration of the inhibitor could be decreased without any other variation which would affect the rate of the reaction.

## *Material and methods.*

All experiments were carried out in a phosphate buffer solution of  $p_H$  7.4. In a few preliminary experiments a crude extract of rat liver was used as catalase preparation, but most of the experiments were carried out with a purified preparation from horse liver for which the author is indebted to Prof. D. Keilin. Just before the experiment, 0.1 ml. of this preparation was diluted with 50 ml. 0.01 *M* phosphate buffer. The stock solution of hydrogen peroxide was Merck's perhydrol (about 9.5 *M*), of which 1.0 ml. was diluted with 11.5 ml. water. This dilute solution was also freshly prepared. For the measurement of enzyme

<sup>1</sup> A few preliminary experiments were carried out in the Pathological Department, University College Hospital, London. The author wishes to express his gratitude to Prof. A. E. Boycott for the hospitality offered to him and to Prof. G. P. Wright for his help.

activity, with and without inhibitor, the usual conical Warburg flasks with one side bulb were used. The flasks were filled as follows:

Main vessel	1.98 ml. 0.01 <i>M</i> phosphate buffer solution + 0.02 ml. catalase solution + 0.25 ml. water or inhibitor
Side bulb	0.25 ml. hydrogen peroxide solution.

The final concentrations were therefore:

Phosphate buffer	0.008 <i>M</i>
Hydrogen peroxide	0.076 <i>M</i>
Catalase	62500-fold dilution of the pure preparation.

The flasks were then attached to their manometers and placed in a bath kept at or slightly below room temperature (11–18°). The reaction was started by tipping the hydrogen peroxide into the main vessel from the side bulb. In a single experiment the reaction rates with different concentrations of a given inhibitor were measured and compared with the rate with the unpoisoned enzyme.

For the study of the reversibility of the inhibition, special flasks were made by Messrs W. Flaig and Sons, London. They are of conical shape and carry two side bulbs that branch off from a common stem (see Fig. 1). The contents of the two side bulbs can be mixed first and then later the mixture can be emptied into the main vessel. The experiments were carried out in the following way. Two flasks of the type described were prepared as follows:

Fig. 1.

Flask no. ...	1	2
Main vessel	1.80 ml. 0.01 <i>M</i> phosphate buffer + 0.225 ml. hydrogen peroxide solution + 0.225 ml. water	1.80 ml. 0.01 <i>M</i> phosphate buffer + 0.225 ml. hydrogen peroxide solution + 0.225 ml. inhibitor solution
Side bulb I	0.18 ml. 0.01 <i>M</i> phosphate buffer + 0.02 ml. catalase solution + 0.025 ml. inhibitor solution	— As in side bulb I of flask No. 1 —
Side bulb II	0.025 ml. hydrogen peroxide solution	As in side bulb II of flask No. 1

The reaction in each flask is started by mixing the solutions in the two side bulbs and after a suitable time, 5 to 10 min., the mixed content of the side bulbs is tipped into the main vessel. As can be seen from the data given above, the concentration of poison, equal for both flasks during the first reaction period, is maintained at the original level in flask No. 2, whereas in flask No. 1 a tenfold dilution of inhibitor takes place. In addition to this change in inhibitor concentration, an unavoidable dilution of the enzyme takes place, but under the conditions of the experiments this dilution has no influence on the reaction rate, a fact, for which flask No. 2 serves as a control. The data of the experiments given below show that the readings in flask No. 2 always give a smooth curve, without break at the point of dilution. As is well-known, the rate of the catalase reaction does not remain constant for long periods, and the experiments were therefore kept as short as possible.

*Experiments.*

The substances studied were in the first instance those catalase poisons that were likely to be useful as catalase inhibitors in tissues, but as the method described was found simple and gave definite results, it was applied to other catalase inhibitors the mechanism of which is still uncertain.

*Hydroxylamine.* The action of hydroxylamine on catalase was discovered by Jacobson [1892] and was later studied by Senter [1905]. More recently Yakushiji [1933] and Shibata and Yakushiji [1933] used hydroxylamine to prove their theory that the decomposition of hydrogen peroxide by catalase is part of the assimilation process in green plants, identical with the so-called Blackman reaction, which had already been compared with the action of catalase by Willstätter and Stoll [1918] and by Warburg and his collaborators [see Warburg and Uyesugui, 1924; Yabusoe, 1924; Warburg, 1925]. According to Shibata and Yakushiji, hydroxylamine inhibits photosynthesis in concentrations which have no effect on respiration.

Table I. *Inhibition of catalase by hydroxylamine hydrochloride.*

Temperature 16.2°.						
Flask no.	...	...	1	2	3	4
Hydroxylamine hydrochloride concentration			0	$10^{-6} M$	$10^{-5} M$	$10^{-4} M$
$\mu$ l. $O_2$ liberated: 0-2.5 min.			141	51	9	1.5
2.5-5 "			62.5	40	10.5	1
5-7.5 "			44	29	9.5	2
7.5-10 "			—	25	9.5	2
Remaining activity as % of that in flask no. 1			First 2.5 min.	36	6.5	1
			First 5 "	45	9.5	1

Table II. *Reversal of hydroxylamine hydrochloride inhibition.*

Temperature 16.6°. Contents of side bulbs I and II mixed at 0 min.; content of side bulbs tipped into main vessel at 10 min.

Flask no.	...	...	1	2
Initial hydroxylamine concentration			$10^{-4} M$	$10^{-4} M$
Final hydroxylamine concentration			$10^{-5} M$	$10^{-4} M$
$\mu$ l. $O_2$ liberated: 0-5 min.			0.75	1.5
5-10 "			0.75	2
10-15 "			16	1.5
15-20 "			16	3

Tables I and II give the results of my own experiments with hydroxylamine hydrochloride. Table I shows the influence of different concentrations of the drug on the rate of hydrogen peroxide decomposition and Table II demonstrates that the inhibition is a reversible one: after dilution the reaction rate is considerably greater than in the control in which the concentration of hydroxylamine has been maintained. The results are shown graphically in Figs. 2 and 3.

*Hydrazine, phenylhydrazine.* The inhibition of catalase by the latter substance has already been described [Loew, 1901; Yamasaki, 1921]. Tables III and IV show that both substances are much less powerful inhibitors than hydroxylamine. They both give reversible inhibitions, but as hydroxylamine seems to be the most suitable and the most active representative of this group of inhibitors, the experiments need not be reproduced *in extenso*.

*Sodium azide.* The inhibition of catalase by azide has only very recently been discovered [Keilin and Hartree, 1934]. It is interesting to note that azide also inhibits slightly the catalytic decomposition of hydrogen peroxide by colloidal platinum [Oliveri-Mandalà, 1929; see also Audrieth, 1934]. The action of azide

is especially interesting in connection with the fact that azide also gives a definite methaemoglobin compound [Keilin, 1933].

Table V shows that sodium azide is a very powerful inhibitor of catalase. Under the conditions of our experiments only about one-fifth of the activity remains with a concentration of azide as low as  $10^{-6} M$ .

The action of sodium azide on catalase is completely reversible (see Table VI).

*Monoethyl peroxide.* That monoethyl peroxide is not a substrate for catalase action has been long known [Bach and Chodat, 1903]; that it is an inhibitor of catalase was shown by Stern [1932]. That monoethyl peroxide combines with methaemoglobin has been shown by Keilin and Hartree [1935], who studied the

*Potassium chlorate, potassium perchlorate.* The salt inhibition of catalase has often been studied [see Stern, 1932] and, since it did not appear likely that these inhibitions would prove useful for the purpose of our investigation on tissues, only a few substances were examined. Among these, chlorate and perchlorate have been found to be relatively powerful inhibitors [Senter, 1903; 1905]. The effects of different concentrations of these salts are given in Tables IX and X. The reversal experiment reveals an interesting difference in the mechanism of action of the two substances: the inhibition by chlorate is irreversible (Table XI), whilst that by perchlorate is reversible (Table XII).

*Mercuric chloride.* Mercuric chloride inhibition of catalase is well known. It is only one of the many poisoning effects of this substance on enzymic reactions. Hata [1909] was the first to prove the reversible action of mercuric chloride on amylase and on proteolytic enzymes [see also Krebs, 1930; 1931]. The work of Hata makes it probable that the effect of mercuric chloride on catalase is reversible, but Stern assumes it to be irreversible. That the mercuric chloride inhibition is in fact reversible can easily be demonstrated [see Table XIV],

but on comparing the data with those given in the preceding Table XIII, one must conclude that recovery is not complete, an irreversible effect is superimposed upon the reversible one, a mode of action comparable with the mechanism of the mercuric chloride inhibition of urease [Sumner and Myrbäck, 1930].

*Resorcinol.* For literature see Euler [1934]. The results of our experiments are given in Tables XV and XVI. Resorcinol inhibits slightly and its action is reversible.

*Benzidine*, *p*-phenylenediamine, *m*-phenylenediamine. As the first two of these substances can act as substrates for peroxidase, it was interesting to see what influence they have on catalase. Tables XVII and XVIII show that they are both inhibitors of catalase, although not very powerful ones. Both inhibitions are reversible (see Tables XIX and XX). Since *m*-phenylenediamine, which does not act as a substrate for peroxidase, has an inhibitory action on catalase (Tables XXI and XXII), similar to that of *p*-phenylenediamine, it is unlikely that the inhibitory action of *p*-phenylenediamine depends on that part of the molecular structure which makes it a substrate for peroxidase.

## DISCUSSION.

The study of the mechanism of catalase inhibitors shows that all those substances that are known to give methaemoglobin compounds act as reversible inhibitors of catalase. To this group belong azide, monoethyl peroxide, sulphide and cyanide. That all these substances act as catalase inhibitors is certainly to be considered as a strong argument in favour of the conception of catalase as a haemin compound. Whether the action of hydroxylamine can be explained on similar lines still remains doubtful. One other substance which is known

to combine with methaemoglobin, *viz.* fluoride, was tested under the same conditions at the suggestion of Prof. Keilin, but was found to be ineffective as an inhibitor in concentrations as high as  $10^{-3}$  *M*. It is interesting to note that Lipmann [1929] found a considerable inhibitory effect of fluoride on the hydrogen peroxide decomposition by inorganic iron. From the dissociation curve of fluoromethaemoglobin measured by Lipmann, the affinity of fluoride for methaemoglobin does not appear to be great and it is therefore possible that the conditions of our experiments in which the catalase is saturated with substrate are unfavourable for detecting slight inhibitory effects.

The reversible inhibition by mercuric chloride may serve to demonstrate that the reversibility, as such, is not a sufficient indication as to the point of attack of the inhibitor; as this effect of the poison is similar to its effect on other enzymes, it seems most likely that it acts on the non-haemin part of the enzyme molecule.

#### SUMMARY.

The action of catalase poisons is measured manometrically and a manometric method for the study of reversibility of catalase inhibitions is described.

The following substances are found to give reversible inhibitions: sodium azide, hydroxylamine, hydrazine, phenylhydrazine, monoethyl peroxide, potassium perchlorate, resorcinol, *p*-phenylenediamine and *m*-phenylenediamine. The mercuric chloride inhibition is partly reversible. Potassium chlorate gives an irreversible inhibition.

The author is most gratefully indebted to the Academic Assistance Council for a grant, to Sir J. Barcroft for his encouragement and hospitality in his laboratory and to Prof. D. Keilin for much help and advice.

# CCLXXIV. STUDIES ON PANCREATIC PROTEINASE. I.

By LIONEL FARBER AND ARTHUR MARSHALL WYNNE.

*From the Department of Biochemistry, University of Toronto, Toronto, Ontario.*

*(Received August 17th, 1935.)*

IN the extensive literature concerning the nature and action of trypsin there appears to be no record of a systematic study of factors affecting the earliest stage of protein breakdown by this enzymic complex or by its isolated proteinase component. Waldschmidt-Leitz and his collaborator [1931; 1932; 1933] have shown that the trypsin complex can be separated into several components each of which effects, characteristically, the degradation of substances of more or less definite complexity or structure. Systematic examination of the kinetic behaviour of each enzyme, acting on suitable substrates, should lead to a better understanding of the complex as a whole and should assist in clarifying certain problems concerning which the literature is sometimes inconclusive and contradictory. Estimations of the increasing amino-nitrogen resulting from the action of trypsin on a protein reveal, by themselves, nothing more than the additive effects of the enzymic components acting upon their respective substrates. Such experimental data have only a very limited value in elucidating the nature of the action of any single component.

In the present work attention has been directed toward the first observable stage of protein degradation, namely the process which renders the protein soluble in trichloroacetic acid solution under the conditions defined later. Very little is definitely known as to the nature of this first stage. It probably represents the rupture of a relatively small number of linkages, resulting in the liberation of molecular aggregates essentially similar to the original molecule but of lower molecular weight. Similar conclusions were reached by Bayliss [1907-08], Sherman and Neun [1918], Vahlteich [1929], Blagoveschensky and Sossiedov [1933], Grabar [1933], Sreenivasaya *et al.* [1934]. By definition the change may be regarded as being due to the proteinase. Without attempting to separate the proteinase from the other enzymes of the trypsin complex, studies have been made of the effects of several factors on the initial rate of the first hydrolytic process. By confining attention to this initial constant velocity the influence of the other enzymes can, at this stage, safely be regarded as being practically negligible. This conclusion is supported by experiments such as that summarised in Table I where it is seen that during the first 2.5 min. of hydrolysis 50% of the original protein was rendered soluble in 5% trichloroacetic acid although amino-nitrogen accumulated to the extent of only slightly more than 1% of the amount present after two weeks' action.

The present paper is concerned with the following aspects of the "first-stage" hydrolysis:

(1) Comparison of the rate of this hydrolysis with that of amino-nitrogen accumulation.

(2) Comparison of the rates of hydrolysis of various proteins.

(3) The influence of substrate concentration on the initial velocity of hydrolysis.

- (4) The relation between enzyme concentration and initial velocity.
- (5) The influence of hydrogen ion concentration on the initial velocity.
- (6) The course and order of the reaction.

#### *Materials.*

*Substrates.* The substrate chiefly employed was Kahlbaum's "casein (Hammarsten)" containing 15.4% nitrogen and 0.8% phosphorus. Stock solutions in buffer ( $p_H$  8.7), kept at 8° for 2 to 3 weeks remained perfectly clear and unchanged in the presence of octyl alcohol. Other proteins used were Merck's ovalbumin, haemoglobin, fibrin and a sample of zein prepared from maize.

*Buffer.* M/5 phosphate-borax-sodium hydroxide buffer,  $p_H$  8.7.

*Precipitant.* To the sample of the digestion mixture was added an equal volume of 10% trichloroacetic acid. This amount was sufficient not only to cause complete precipitation of the proteins present in 1% concentration but also to stop the enzyme action.

*Enzyme.* Dry fat-free pancreas powder (passed through No. 80 mesh) was prepared by a method essentially similar to that of Willstätter and Waldschmidt-Leitz [1921; 1923]. The solvents used were acetone, acetone-ether and ether. The proteinase activity of the resultant powders remained practically unchanged for at least 20 months when the material was stored in a desiccator at 8–10°.

The enzyme solutions used in all experiments except those which concern the relation between enzyme concentration and reaction velocity were prepared in the following manner. A weighed portion of pancreas powder was triturated in a glass mortar with successive portions of the extracting solution (buffer solution or 50% aqueous glycerol) until a uniform suspension of thin consistency was obtained. This was transferred to a flask and the mortar was washed with extracting solution; for 8 g. powder a total of 100 ml. of solution was used. After the addition of a few drops of octyl alcohol the combined liquids were shaken for 3 hours in a water-bath at 25°; the suspension was then centrifuged at 1200 r.p.m. for 3 hours after which the supernatant fluid was passed through a Seitz filter. A perfectly clear, slightly yellow solution was obtained. When kept at 8° extracts of the powdered gland with phosphate-borax buffer ( $p_H$  8.7) lost no activity in 2 weeks; 1% sodium carbonate extracts lost 54% in 10 days and distilled water extracts lost 63% of their activity in the same time. On the other hand, 50% aqueous glycerol extracts were completely stable for at least 3 months. This advantage is, to some extent, offset by the fact that glycerol appreciably retards the action of the enzyme.

For the investigation of the influence of enzyme concentration on reaction velocity the enzyme solutions were prepared by extracting weighed portions of pancreas powder with 10 ml. buffer solution for 10 minutes, vigorously shaking the suspension. The supernatant fluids obtained after 10 minutes' centrifuging at 1800 r.p.m. were used immediately.

All enzyme solutions were adjusted, when necessary, to the  $p_H$  of the buffer before use. It was not found necessary to add any activator such as enterokinase.

#### *Analytical methods.*

In view of the objections, previously mentioned, which apply to the use of amino-nitrogen determinations in the solution of the problems under investigation, the rate of disappearance of the protein itself was adopted as the most suitable measure of proteinase activity. For this purpose either of two procedures was employed.

*Procedure 1.* In this case the entire contents of a digestion tube were treated in obtaining a single reading, several such tubes being used to establish a progress curve. Centrifuge-tubes (50 ml.) were employed, each containing 4 ml. of substrate solution adjusted to the proper  $p_H$  and warmed to 25°. At a convenient time, measured on a stop-watch and recorded as zero time, 1 ml. of enzyme solution (25°) was pipetted into the tube, an operation requiring about 2 sec. After the desired time interval 5 ml. of 10% trichloroacetic acid solution were quickly pipetted into the digestion mixture; the precipitate was spun down, washed once with 5% trichloroacetic acid, recentrifuged and dissolved in 3 ml.  $N/10$  NaOH; the solution was transferred quantitatively to a 10 ml. volumetric flask and made up to volume. Duplicate samples (1 or 2 ml.) were analysed for nitrogen in a micro-Kjeldahl apparatus of the improved Parnas-Wagner type; approximately  $N/125$   $H_2SO_4$  and  $N/125$  NaOH solutions were used for absorption and titration respectively. In order to establish the initial reaction velocity corresponding to a given set of conditions it was customary to employ at least 3, usually 4, such digestion mixtures identical in every respect but incubated for different periods. Usually it was not necessary to allow the most prolonged digestion to proceed for more than 90 sec. A zero-time reading was obtained by allowing the enzyme and precipitant to flow simultaneously into a tube containing substrate or by adding the trichloroacetic acid first and then the enzyme, the precipitate being treated and analysed in the usual way. By plotting hydrolysed protein-nitrogen against time, progress curves were obtained from whose linear portions initial velocities were calculated.

*Procedure 2.* In this case successive samples were removed from a single digestion mixture contained in an L-tube rocking in a bath at 25°. From the progress curve the initial velocity of hydrolysis was determined. In view of the speed of the reaction it was necessary to observe very carefully certain precautions. The substrate and any necessary buffer solution were first introduced into the tube and allowed to attain the temperature of the bath. A stop-watch was then started and at a convenient point (zero time) the enzyme solution, previously warmed to 25° and contained in a small open glass vessel, was dropped into the tube; the addition and diffusion of the enzyme were complete in about 2 sec. The total volume and  $p_H$  were accurately known. Shortly after the addition of the enzyme mixture a 4 ml. sample was quickly pipetted into a 50 ml. centrifuge-tube containing 4 ml. of 10% trichloroacetic acid. The same pipette was used for subsequent samples and was rinsed with digest liquid before use. With practice it was possible to remove the first sample 20 or 30 sec. after the beginning of the reaction and subsequent samples at 20-sec. intervals if desired. Residual protein-nitrogen was determined as previously described.

In both procedures it was necessary to take account of the acid-insoluble nitrogen contained in the enzyme solution. A quantity of the solution equivalent to that used in the digestion was added to a quantity of water equal in volume to that of substrate *plus* buffer; samples were treated with trichloroacetic acid in the usual way and the total nitrogen of the precipitates was determined. The values so obtained were subtracted from the total protein-nitrogen of the digestion samples.

Occasionally, it was desirable, in both procedures, to adopt considerably longer time intervals than those indicated.

*Determination of amino-nitrogen.* Amino-nitrogen was calculated after titrating the liberated carboxyl groups according to the method of Willstätter and Waldschmidt-Leitz [1921], using  $N/50$  alcoholic KOH and thymol blue.

## EXPERIMENTS AND DISCUSSION.

*Comparison of the rate of the "first-stage" hydrolysis with that of amino-nitrogen accumulation* (Table I). Reference to the results has already been made. They show that determinations of amino-nitrogen in the very early stages of hydrolysis do not permit an accurate evaluation of the proteinase activity. Analysis of residual protein, on the other hand, constitutes a reliable index of this activity.

Fig. 1. Rates of hydrolysis of caseinogen (1), fibrin (2), haemoglobin (3), zein (4) and ovalbumin (5), by the pancreatic proteinase.

*Comparative rates of hydrolysis of different proteins.* The rates of hydrolysis of five proteins at 25°, in buffered digests at  $p_H$  8.7 and present, initially, in 0.92% concentration were followed by procedure 2, the same amount of enzyme being used in all cases. The results, expressed in Fig. 1, are of interest for the following

reasons. (1) Of the soluble proteins tested caseinogen was the most rapidly hydrolysed. (2) The order in which the proteins can be arranged on the basis of initial rates of hydrolysis (e.g. for 1 min.) is quite different from the order of arrangement based on 5 min. hydrolysis. This difference emphasises the importance of distinguishing, in kinetic experiments, between initial rates and rates calculated from the results of more prolonged digestions. (3) Ovalbumin, known to be very resistant to prolonged tryptic action, was hydrolysed for a short period at a rate comparable with that of the other proteins; subsequently the hydrolysis was very slow. The experiment suggests that an anti-proteinase substance may have been liberated during the very early hydrolysis. In this connection it is of interest to recall that Balls and Swenson [1934] showed that the proteinase inhibitor of egg-white is found in the watery fraction of the white and that this watery fraction is formed during storage of the egg by proteolysis of the thick white.

*Relation between substrate concentration and initial velocity of hydrolysis.* Northrop's studies on the kinetics of trypsin digestion [1924; 1932-33; Northrop and Kunitz, 1932-33] led him to the view that the enzyme does not form a compound with the substrate and that the speed of the hydrolysis is proportional to the concentration of free enzyme, i.e. enzyme not combined with products. This view of the mode of action of trypsin is opposed to the well-known theory of Michaelis and Menten [1913] which is an elaboration of those of Brown [1902] and of Henri [1905]. According to this theory enzyme-substrate compound formation takes place and the speed of the observed reaction depends directly upon the concentration of the compound. The theory was originally founded on experiments with the invertase-sucrose system; in recent years several other enzyme systems have been shown to behave in a manner predictable by the theory.

The investigation of the applicability of the equation of Michaelis and Menten to a given enzyme system is of primary importance in deciding whether or not the enzyme concerned combines with the substrate to yield a compound whose concentration determines the rate of the observed reaction. In such experiments it is not sufficient to calculate the substrate concentration corresponding to half-maximum velocity and to assume that this value represents the dissociation constant of the enzyme-substrate compound. Further analysis of the data is required in order to determine whether combination according to the mass law actually takes place.

A series of caseinogen solutions of different concentrations was prepared from three stock solutions, 5, 1.5 and 0.1%. Two buffer extracts of powdered pancreas were used, the first (Enzyme 1) prepared by extraction with  $M/5$  potassium chloride-sodium borate solution  $p_H$  9.3 and the second (Enzyme 2) with  $M/5$  phosphate-borate-sodium hydroxide solution  $p_H$  8.7. The final volume of each digest, 5 ml., was adjusted by adding to the substrate solution a suitable amount of the appropriate buffer prior to the addition of the enzyme. The initial rate of disappearance of acid-insoluble protein was followed by procedure 1. Typical results are recorded in Tables II and III, the enzyme preparations being 1 and 2 respectively. The values of  $K_s$  and  $V_{max}$  in the equation of Michaelis and Menten were obtained by an algebraic method.

The agreement between observed and calculated values is sufficiently close to justify the conclusion that the initial velocity of hydrolysis is predictable by the theory and that caseinogen enters into combination with the proteinase. The difference in the two values of  $K_s$  is not easily explained without further investigation, but it may be due to the use of different buffers at slightly different  $p_H$  levels. In another experiment in which a 30% glycerol extract of the powder

was used the agreement between calculated and observed values of  $v$  was somewhat better than that indicated in Table III, but the value of  $K_s$  was considerably lower than the others; the difference was possibly associated in some manner with the known inhibitory effect of glycerol on the activity of the proteinase system. In the range of concentration above 1.5% the observed velocity was always less than the calculated. It is possible that here, as in the case of the invertase-sucrose system [Nelson and Schubert, 1928] the falling off of the observed velocities in the case of the higher substrate concentrations is due to a decrease in the relative water concentration. But, with the proteolytic system, no direct study of this point has been made although experiments on the effects of carbohydrates on proteinase activity, to be described in a later paper, strongly suggest that variations in the relative water concentration seriously affect the activity of the enzyme. The possibility of the combination of the enzyme with two or more molecules of substrate to form an inactive compound [cf. Murray's experiments on liver esterase, 1930] was tested by the method of Lineweaver and Burk [1934]; examination of the available data showed that the falling off was not due to such a combination.

*Relation between enzyme concentration and initial velocity of reaction.* The results in Table IV show that the initial velocity of hydrolysis ( $v$ ) varies directly with the enzyme concentration ( $E$ ). Such a relationship is to be expected on the

basis of the theory of Michaelis and Menten. This finding is in opposition to that recently reported by Bergmann and Pojarlieff [1934] who observed that the initial velocity of collagen breakdown by trypsin was proportional to the square root of  $E$ ; a similar observation was made by Bergmann and Föhr [1932] in experiments in which the tryptic digestion of gelatin was followed by an optical method. In both cases, however, consideration of the diffusion factor must affect any generalised interpretation of the results. Bayliss [1925] observed that, depending upon the stage of protein breakdown by trypsin measured by changes in electrical conductivity, the relationship between  $E$  and  $v$  varied: in the early stages  $v$  was directly proportional to  $E$ , but in later stages  $v$  was proportional to a number of roots of  $E$ . Northrop examined the question in some detail: although his data [1924, p. 449] indicate a direct relationship in the early stage at  $40^\circ$ , yet at  $0^\circ$  he found that the Schütz rule was applicable in a rather restricted sense [1924, p. 723]. The complexity of "trypsin" and the variety of reactions catalysed by its various components make it imperative that, in considering the relationship under discussion, attention be confined at any time to only one of the several enzyme systems. Failure to do this leads to much confusion.

Table IV. *Relation between enzyme concentration and initial velocity of hydrolysis.*

16	0.0581	0.0590

*Influence of  $p_H$  on initial velocity of hydrolysis.* The substrates were caseinogen, haemoglobin and fibrin, present in the digestion mixtures in 0.80 %, 0.79 % and 0.55 % concentrations respectively. The enzyme preparation was a phosphate-borax extract and procedure 2 was used. Substrate solutions were prepared by titrating measured amounts of stock solutions to the desired  $p_H$  with  $H_2SO_4$  or NaOH solution. The appropriate buffer solutions were then added in sufficient quantity to yield known volumes of substrate solution of the desired concentrations. The initial  $p_H$  of each digestion mixture was assumed to be identical with that of a control mixture, determined electrometrically; the controls were in all respects similar to the experimental digests except that boiled enzyme was used in place of the active preparation, the  $p_H$  of the boiled and active enzymes having previously been adjusted to the same level. Frequent tests showed that during the short reaction periods adopted (up to 60 sec.) no detectable change in  $p_H$  occurred. It was therefore possible to correlate accurately determined values of the initial velocity of hydrolysis with  $p_H$  values which were known not to vary throughout the observed course of the reaction. The results are expressed in Fig. 2 where it is seen that all three substrates have the same optimum,  $p_H$  8-9.

In the case of enzymes acting upon substrates which are only very slightly ionised, Euler *et al.* [1924] and Josephson [1925] have shown that the speed of

the reaction is determined by the fraction of the total enzyme existing as undissociated enzyme-substrate compound. This fraction is, in turn, a function of several factors, namely hydrogen ion concentration, acid dissociation constant of the enzyme-substrate compound, substrate concentration and the Michaelis constant. With substrates, such as proteins, which may be very appreciably ionised in solution the equation of Euler *et al.* in its simple form would not necessarily be expected to hold. Northrop [1922-23] observed a close similarity

Fig. 2. Effect of  $p_H$  on the initial velocity of hydrolysis of various proteins by the pancreatic proteinase.

between the titration curves of caseinogen, haemoglobin and gelatin on the one hand and, on the other, the  $p_H$ -activity curves obtained in experiments on the tryptic hydrolysis of these proteins. From this similarity he concluded that the concentration of protein anions at various  $p_H$  levels determined the degree of digestibility of the protein. Trypsin itself he regarded as a strong base behaving as a univalent cation in solutions of  $p_H$  2 to 10, the isoelectric point being at about  $p_H$  10.

Table V.

	Caseinogen	Fibrin	Haemoglobin
Isoelectric point	4.70	5.80*	6.74
$p_H$ corresponding to 50% of maximum activity	6.90	7.20	7.63

\* Vonk [1931]—point of minimum swelling in phosphate buffer.

On comparing the isoelectric points of the proteins investigated with the  $p_H$  values corresponding to 50% of maximum activity, the relationship in Table V is observed. As the isoelectric point decreases, the lower  $p_H$  limit for proteinase activity also decreases. This supports Northrop's conclusion that the enzyme is active only on protein anions. As the  $p_H$  approaches 8 the proteinase may begin to lose its positive charge and, in consequence, its effectiveness; but the increased concentration of protein anions balances the loss of activity due to this cause. The hydrogen ion concentration therefore exercises its influence on the proteinase-protein system in two directions: (1) on the ionisation of the protein, (2) on the ionisation of the enzyme or of the enzyme-substrate compound. The identity of the  $p_H$  optimum of the three proteins investigated seems to be well established but the limited data do not permit the assumption that other proteins, under the same conditions, would have the same optima.

*The course of proteinase action.* The application of the expression for a uni-molecular reaction to the course of "trypsin" digestion has frequently been attempted, but usually with very little success. Other equations containing arbitrary constants have also been proposed to express the course of the reaction. In the present work it has been observed repeatedly that the course of the reaction was linear during the breakdown of a considerable portion of the substrate—in some cases, as much as 65%. Subsequently, the rate of reaction diminished when complicating factors became significant. The true course of the action of the proteinase must therefore be regarded as being of zero order.

Incidentally, the adoption of initial velocity measurements as the basis of kinetic studies provides a method for the comparison of the proteinase activities of different enzyme preparations. Accordingly, the proteinase unit may be defined as the amount of enzyme which causes caseinogen breakdown at an initial rate equivalent to 0.10 mg. nitrogen per sec. under the following standard conditions: total volume of digestion mixture, 5 ml.; caseinogen concentration, 1%;  $p_{\text{H}}$  8.6–8.7 controlled by phosphate-borax buffer; temperature 25°.

#### SUMMARY.

1. With the aid of micro-methods, permitting the measurement of the initial velocity of protein hydrolysis, studies of the activity of the pancreatic proteinase have been made. The rate of protein disappearance was much greater than that of amino-nitrogen accumulation. The latter is not a satisfactory index of the activity of the proteinase.

2. The rates of hydrolysis of various proteins were compared.

3. The initial rate of hydrolysis varied with the substrate concentration in a manner predictable by the theory of Michaelis and Menten.

4. The initial rate of hydrolysis varied directly with the concentration of enzyme over a wide range.

5. The influence of  $p_{\text{H}}$  on the rate of hydrolysis of three proteins was investigated.

6. The reaction was shown to be one of zero order during the hydrolysis of a considerable fraction of the protein.

7. The results are discussed in relation to those of previous investigators.

# CCLXXV. STUDIES ON PANCREATIC PROTEINASE.

## II. THE EFFECTS OF VARIOUS COMPOUNDS ON THE ACTIVITY OF THE ENZYME.

BY LIONEL FARBER AND ARTHUR MARSHALL WYNNE.

*Department of Biochemistry, University of Toronto, Toronto, Canada.*

*(Received August 17th, 1935.)*

In the foregoing paper [Farber and Wynne, 1935] methods were described for the study of the activity of pancreatic proteinase. These methods have been used in a study of the effects on the activity of the enzyme of chemical substances of various types, including carbohydrates, glycerol, amino-acids, triglycerides, bile and bile salts, indicators and dyes, salts of heavy metals and other salts.

As substrate Kahlbaum's "casein (Hammarsten)" was used throughout, the concentration in the digestion mixtures being 0.80 % in the glycerol experiments and 0.90 % in all others. The digests were buffered at  $p_H$  8.7 with  $M/5$  phosphate-borax buffer; solutions of the various compounds were, whenever necessary and practicable, adjusted to  $p_H$  8.7. The exceptions were those salts which formed precipitates at this alkalinity. The relative rates of hydrolysis listed in the tables which follow have been calculated from initial rates which, in turn, were based on determinations spaced, usually, at intervals of 20 sec. The total period of digestion, as a rule, was not more than 60 sec.; changes in  $p_H$  during such short time intervals were negligible. Accurate estimations of initial velocity of hydrolysis were readily made with the aid of the procedures described in the previous paper.

### EXPERIMENTAL RESULTS.

*Carbohydrates.* Stock buffer solutions of several carbohydrates having the following concentrations were prepared; sugars, molar; dextrin and soluble starch, 18 %; gum acacia, 9 %. Portions of the solutions were added to the digestion mixtures to give the concentrations listed in Tables I and II. Two enzyme preparations were used: the first, a phosphate-borax buffer extract of powdered pancreas prepared as described in the previous paper and used in the experiments with sucrose, maltose and lactose; the second, a 1 %  $Na_2CO_3$  extract

Table I. *The effects of sugars on the activity of the proteinase.*

The figures in columns 2 to 6 represent the initial velocity as % of the initial velocity of hydrolysis in the control digest.

Sugar	Concentration $M$					% inhibition at 0.5 $M$
	0.02	0.04	0.10	0.20	0.50	
Glucose	—	90	—	82	58	42
Fructose	—	71	—	63	55	45
Galactose	—	78	—	73	60	40
Sucrose	97	94	89	81	57	43
Maltose	—	88	—	81	61	39

Melizitose	—	100	99	83	76	24

Table II. *Effect of polysaccharides on proteinase activity.*

The figures represent initial velocity as % of that in control digests.

Substance	Concentration %					
	0.36	0.72	1.8	3.6	4.5	9.0
Dextrin	—	95	90	88	—	85
Soluble starch	—	100	86	78	—	75
Gum acacia	95	—	96	—	104	—

used with the other carbohydrates. Procedure 1, previously described (p. 2315), was used for the preparation of the digests and for the determination of residual protein. The results are summarised in Tables I and II.

*Glycerol.* For these experiments the enzyme solution was prepared by precipitating an aqueous extract of pancreas powder by adding *N* acetic acid, concentrating the filtrate at low temperature to one-tenth the volume and neutralising the concentrate with NaOH. Procedure 1 was used throughout; the total volumes of the digestion mixtures were identical (5 ml.), the relative proportions of glycerol and water having been varied to give the glycerol concentrations listed in Table III.

Table III. *The effect of glycerol on proteinase activity.*

Concentration		
<i>M</i>	%	% inhibition
0.22	2	11
0.44	4	19
0.88	8	40
1.30	12	63
1.74	16	73

The results in Tables I, II and III show that both sugars and glycerol, present in moderately high concentrations, retard the action of the enzyme. The individual sugars exhibit differences in their effects at the lower concentrations: at 0.5 *M* concentration, however, the differences are less marked except in the case of lactose and melizitose. Stock solutions of these sugars and of maltose yielded, on standing at 8°, small deposits of crystals increasing in amount in the order, maltose, lactose, melizitose, but slight warming was sufficient to bring the sugars into solution again. The inhibitory powers of the three sugars at 0.5 *M* concentration decreased in the same order as their solubilities. Although the various sugars in the lower concentrations exhibit differences in their effectiveness as inhibitors, the general similarity of their effects (excluding those of lactose and melizitose) in the higher range of concentration leads to the conclusion that in this range the retardation of the activity of the enzyme is very largely a function of the molar concentration of the compounds; the nature of the sugar is of secondary importance. This view is supported by the data in Tables I and II, and in Table IV where the effects of mixtures of sugars are shown.

Table IV. *Effect of sugar mixtures on proteinase activity.*

Substance	% inhibition
0.25 <i>M</i> glucose	
+	
0.25 <i>M</i> fructose	47
0.25 <i>M</i> glucose	
+	
0.25 <i>M</i> galactose	48

Inhibition by sucrose was directly proportional to the concentration in the range 0.04 to 0.5 *M*. In the case of lactose a similar relationship was observed to hold from 0.1 to 0.5 *M*; with the lower concentrations such proportionality did not exist, owing perhaps to the relatively greater influence in the low concentrations of the reducing group of the sugar. It is proposed in further studies to compare the effects of low concentrations of various sugars, reducing and non-reducing, in order to determine more exactly the relation between the reducing powers of the sugars and their inhibitory properties. The degree of inhibition by glycerol was, within experimental error, directly proportional to the concentration between the limits 2 and 12 %.

It may be suggested that the inhibition by glycerol and the sugars is closely related to the well known fact that these compounds become hydrated in solution, possibly through coordinate linkages of the atoms of the hydroxyl groups with water molecules in the manner indicated by Jordan-Lloyd and Phillips [1933] in the case of proteins. The degree of hydration of sucrose has been investigated by several workers. McBain and Kistler [1929], who review the earlier literature, obtained evidence from direct measurements by ultrafiltration methods that sucrose in dilute solution is hydrated with not less than 4 molecules of water per molecule of sugar. Scatchard [1921] concluded from an analysis of his own and other data that the formation of a penta- or hexa-hydrate best explained the experimental results, though the concentration affected in some measure the degree of hydration. Total removal of water by hydration increases, of course, with the concentration of the sugar. One may assume also that caseinogen in solution becomes hydrated, possibly by coordinate linkage of water molecules with the atoms of the hydroxyl, carboxyl, amide, amino- and imino-groups, but in the case of proteins accurate assessment of the degree of hydration of the various groups is much more difficult. In any case it is probable that the sugars and glycerol, when added to enzyme-protein solutions, reduce in greater or less degree the effective water concentration by competition with both enzyme and its substrate for water.

*Polysaccharides.* Dextrin and soluble starch as inhibitors were less effective than the sugars; gum acacia was without significant effect (Table II).

*Amino-acids.* The effects of several amino-acids and of asparagine on the activity of the enzyme were examined at  $p_H$  8.7 according to Procedure 1, the enzyme preparation being a 1 %  $Na_2CO_3$  extract of pancreas powder. The results are shown in Tables V and VI.

Table V. *The effects of amino-acids on proteinase activity.*

The figures represent initial velocity as % of that in control digests.

Substance	Concentration <i>M</i>													
	0.0020	0.0024	0.0026	0.0028	0.0030	0.013	0.020	0.024	0.026	0.028	0.030	0.050	0.060	0.075
Histidine	94	—	—	—	—	—	92	—	—	—	—	97	—	—
Phenylalanine	—	97	—	—	—	—	—	94	—	—	—	—	97	—
Cysteine	—	—	82	—	—	100	—	—	110	—	—	—	97	—
			85						109					
Leucine	—	—	—	—	99	—	—	—	—	—	99	—	—	96
Aspartic acid	—	—	—	—	106	—	—	—	—	—	117	—	—	121
Glutamic acid	—	—	—	96	—	—	—	—	—	105	—	—	118	—
Asparagine	—	—	—	—	98	—	—	—	—	—	—	—	—	125

Of the amino-acids examined histidine, phenylalanine and leucine had no very significant effects in the concentrations used. Cysteine (0.026 *M*) exercised a slight accelerating effect in two experiments; with aspartic and glutamic acids

Table VI. *Effect of amino-acid mixtures on proteinase activity.*

The figures represent initial velocity as % of that in control digests.

Mixture	Concentration %			
	0.06	0.30	0.60	1.50
Monoamino-acid mixture prepared from caseinogen	111	115	119	—
Arlington aminoacids	97	—	105	107

and asparagine the activation was somewhat more marked. Activation by the amino-acid mixture (Table VI) was similarly quite definite but the identity of the activator is obscure.

*Triglycerides.* Emulsions (20 % by volume) of triacetin, tributyrin and triolein in 3 % gum acacia were prepared. The first two emulsions were reasonably stable but triolein in gum acacia solution gave a very unstable emulsion which separated, immediately after shaking, into two layers. A very stable emulsion of triolein was obtained with the aid of 0.2 % sodium oleate solution. Portions of the emulsions were transferred to the digestion mixtures to give the concentrations listed in Table VII. Strictly speaking, these cannot be regarded as truly molecular concentrations since the substances, at least in the higher concentrations, were not in true solution.

Table VII. *Effect of triglycerides on proteinase activity.*

The figures represent initial hydrolysis as % of that in control digests.

Substance	Concentration <i>M</i>									
	0.0081	0.020	0.041	0.066	0.081	0.092	0.132	0.184	0.264	0.368
Triacetin	—	—	—	—	—	56	—	41	—	29
Tributyrin	—	—	—	80	—	—	63	—	40	—
Triolein (gum acacia)	95	—	96	—	102	—	—	—	—	—
Triolein (sodium oleate)	104	91	74	—	—	—	—	—	—	—

The three triglycerides, when properly emulsified, had marked inhibitory effects. In the case of triolein emulsified in gum acacia solution the degree of inhibition was relatively very slight but triolein in sodium oleate was definitely inhibitory in a concentration corresponding to 0.04 *M*. Control experiments indicated that part of this effect was due to the sodium oleate. Inhibition by the well-emulsified triglycerides was probably due to the formation of protective films around the micelles of the reacting substances. The opposite effect of emulsions was observed by Wasteneys and Borsook [1928] in experiments on protein synthesis. In this case the emulsion apparently provided means for the extension of the surface area of enzyme or substrate or both.

*Bile and bile salts.* Sodium taurocholate and sodium glycocholate (Eastman) and fresh ox bile were used. The enzyme was a 33 % glycerol extract of pancreas powder. The results are summarised in Tables VIII and IX. They confirm the observations of Ringer [1921; 1922], of Vonk *et al.* [1933] and of others, that in alkaline solution bile and bile salts diminish the rate of breakdown of protein by trypsin. The results with sodium glycocholate are, however, contrary to those of Willstätter and Persiel [1925] who observed that this salt, in 0.002 *M* concentration, had no effect on tryptic activity determined by the increase in acid titratable in alcoholic solution.

Table VIII. *Effect of ox bile on proteinase activity.*

*Indicators and dyes.* In carrying out these experiments the solution of the indicator was first mixed with freshly prepared aqueous enzyme extract and the mixture was allowed to stand before addition to the reaction mixture. 2 ml. portions of enzyme solution were pipetted into several small test-tubes; varying amounts of *M*/5 phosphate-borax buffer solution ( $p_{\text{H}}$  8.7) and of the indicator solution were then added to give the desired concentrations of indicator in a total volume of 3 ml. Control tubes contained 2 ml. enzyme solution and 1 ml. buffer solution. After standing for 20 min. at 25°, 1 ml. indicator-enzyme solution was added to a solution containing 1.5 ml. 3% caseinogen and 2.5 ml. buffer solution; the reaction was followed as in Procedure 1. In experiments in which Procedure 2 was used the reaction mixture contained twice the above amounts of all consti-

tments. The caseinogen concentration in the digests was therefore 0.9%; the concentrations of the indicators shown in Tables X and XI refer to those in the indicator-enzyme solutions before addition to the substrate. The concentrations in the reaction mixtures were, therefore, one-fifth of these values.

Quastel [1931; 1932] has shown that certain indicators and dyestuffs have marked inhibitory effects on the oxidation of glucose, lactate, succinate and formate by *Bact. coli* and on the action of fumarase and urease. Both basic and acidic dyes were toxic toward fumarase, whereas only basic dyes inhibited oxidations by *Bact. coli*. Acidic dyes were entirely inert toward urease although most basic dyes were toxic. These and other observations led Quastel to the conclusion that the groupings responsible for the attachment of urease to its substrate consist of the primary amino-group and the secondary imino-group. Investigations of this kind would appear to offer a very promising approach to the study of the nature of the active groups of enzymes in general. Our own efforts in this direction were concerned with a survey of the effects of representative dyestuffs on proteinase activity with the hope that a subsequent study of the possible protective effects of known chemical compounds in the case of toxic dyes might lead to some understanding of the nature of the chemical groups responsible for the union of the proteinase with its substrate. It has been found however that, even though used in concentrations considerably higher than those which Quastel found to be decidedly toxic in many cases towards the enzymes enumerated above, the dyestuffs examined were quite inert toward the proteinase. Furthermore, the acidic or basic nature of the dye had little or no relation to its effect on the enzyme. The results which are recorded have, therefore, little positive interest. They do suggest that the active group of the proteinase differs from those of the enzymes studied by Quastel. But the question of the degree of purity of the enzyme is one which introduces difficulties of interpretation. It is quite possible that impurities present in the enzyme preparations protected the enzyme from the toxic influence of added dyestuff, though enzyme and dyestuff were in preliminary association for 20 min. Quastel's urease preparation was a partially purified aqueous extract; the fumarase solutions were cell-free preparations made from bacteria, erythrocytes and brain; for the oxidation experiments suspensions of bacteria and of minced muscle were used. Some of these preparations, like the enzyme solutions used in the present work, must have contained large amounts of non-enzymic material. Further work on the influence of dyestuffs on the activity of purified proteinase preparations is now in progress.

**Salts.** In Tables XII and XIII the effects of various salts are recorded. In all experiments the enzyme-salt mixtures were allowed to stand for 20 min. at 25° before addition to the substrate-buffer solution. An aqueous solution of the enzyme was used and the method of preparing the digests was similar to that employed in the case of the indicators. The enzyme solutions containing calcium chloride and lead acetate developed precipitates on standing, the amounts varying with the concentration of the salt. Sodium nitroprusside caused the development of a purple colour in the enzyme solution; the other salts caused no visible effect. The concentrations of the salts given in the tables are those in the enzyme-salt solutions; in the digests the salt concentrations were one-fifth of the recorded values.

Unlike many enzymes the proteinase was apparently unaffected by the presence of salts of the heavy metals in concentrations as high as  $3 \times 10^{-3} M$ .

Each of the compounds calcium chloride, sodium cyanide, potassium ferrocyanide and potassium ferricyanide exercised an activating effect on the pro-

teinase (Table XIII). Some years ago it was generally accepted that calcium salts activate trypsin, but experiments of Waldschmidt-Leitz [1924] caused a revision of this opinion. In the present experiments the activity of the proteinase was definitely stimulated by calcium. It is possible that this activation was due to the removal of concomitant inhibitors present in the rather impure enzyme preparation employed. It is proposed to test this possibility by using more highly purified preparations.

The activation by cyanide was quite definite. Willstätter *et al.* [1926] obtained results which led them to conclude that cyanide inhibits the activity of the protease of the pumpkin. However, Ambros and Harteneck [1929], on examining the problem, showed that the effect was due to the inhibitory influence of cyanide on the peptidases present in the enzyme preparation. The result was a marked reduction in the total acid titratable in alcoholic solution. When the effect on the peptidases was taken into account, the proteinase was shown to be activated by cyanide, a finding with which the present results with pancreatic proteinase are in agreement. Activation by cyanide has been well established in the case of other proteolytic enzymes such as papain and bromelin.

The mechanism of the acceleration of enzyme action by cyanide has, in recent years, been a subject of considerable interest. Krebs [1930] suggested that cyanide activation is due to the removal of toxic heavy metals by the formation of cyanide-metal complexes. In the present work, however, salts of heavy metals in moderately high concentration had no apparent inhibitory or toxic effects even after preliminary association with the enzyme for 20 min. Activation of the enzyme by cyanide cannot, therefore, be explained on the basis of such a detoxication process. Cyanide appears to exercise a positive activating influence; this is true, also, of potassium ferrocyanide and potassium ferricyanide. The explanation in each case must await further experiments.

## SUMMARY.

1. The influence of various chemical compounds on the initial rate of hydrolysis of caseinogen at  $p_{H}$  8.7 by pancreatic proteinase was investigated with the aid of micro-methods for the determination of residual proteins. The substances investigated included carbohydrates, glycerol, amino-acids, asparagine, triglycerides, bile and bile salts, indicators and dyes, salts of heavy metals and other salts.

2. Mono- and di-saccharides in moderately high concentrations (e.g. 0.5  $M$ ) exercised marked inhibitory effects upon the activity of the proteinase. These effects are believed to be largely independent of the configurations of the sugars and to be related to a disturbance of the effective water concentration of the digestion mixture.

3. Dextrin and soluble starch were less effective inhibitors than the sugars. Gum acacia was without significant effect in moderately high concentration.

4. The degree of inhibition by glycerol was in direct proportion to the concentration. The effect observed is believed to be related to a disturbance of the effective water concentration of the enzyme digest.

5. Of the amino-acids investigated, aspartic and glutamic acids exercised definite accelerating effects; acceleration by cysteine was less marked; the others were relatively ineffective.

6. Asparagine caused definite activation.

7. Triacetin, tributyrin and triolein, when properly emulsified, were inhibitory. Unstable emulsions of triolein in gum acacia had no appreciable effect.

8. Fresh ox bile and bile salts were inhibitory.

9. Indicators and dyes, used in concentrations which Quastel found to be inhibitory towards fumarase and urease, had no significant effect on proteinase activity.

10. Salts of heavy metals in concentrations as high as  $3 \times 10^{-3} M$  were without effect.

11. Calcium chloride, sodium cyanide, potassium ferrocyanide and potassium ferricyanide stimulated the activity of the enzyme.

12. Activation of the proteinase by cyanide was apparently not due to removal of toxic heavy metals.

# CCLXXVI. THE AMINO-ACID CONTENT OF WHEAT FLOUR DOUGH.

By LESLIE WILLIAM SAMUEL.

*Rothamsted Experimental Station, Harpenden, Herts.*

*(Received August 23rd, 1935.)*

IN view of a recent paper in this *Journal* by Blagoveschenski and Yurgenson [1935] on the action of flour and yeast enzymes on wheat proteins, it seems of interest to note the results of an investigation of the changes in the amino-acid content of flour dough with time, in the presence and in the absence of yeast, which was undertaken in the latter half of 1933. Blagoveschenski and Yurgenson [1935] concluded that the increased solubility of flour proteins under the influence of flour enzymes was not accompanied by an increase in amino-nitrogen but that the solvent effect of yeast enzymes was due to true proteolysis.

Several investigators have reported an increase in amino-nitrogen content (determined by various methods) of ageing dough in the presence and in the absence of yeast, but Brownlee and Bailey [1930] found a decrease in the amino-acid content of yeasted flour dough during fermentation and attributed this to utilisation of the amino-nitrogen by the yeast.

## MATERIAL AND METHODS.

Five flours were used in this study, the dough formula being, flour 100 g., sugar 2 g., with sufficient salt solution (2½ %) to form a dough of normal consistency. The sugar was dissolved in the salt solution, the flour and liquid incorporated by hand and then mixed for 1 min. in a mechanical kneading machine. Where yeast was used it was added at the rate of 2 g. to the above mix and was dispersed in the liquid, before addition to the flour. The doughs were maintained at 29° and at definite time intervals samples of dough were dispersed in sufficient additional water to give a 1 : 5 extract, by grinding in a mortar and then mixing in a mechanical drink mixer. The liquid was clarified in the centrifuge and the amino-acid content determined by the Brown [1923] modification of the Sørensen [1907, 1, 2] formaldehyde titration as previously described [Samuel, 1934] by titration to  $p_H$  8.0 (thymol blue) before and after the addition of formalin. The results obtained are shown in Table I, and the initial values of the amino-acid content at zero time for the yeasted and unyeasted doughs show that the technique yields reproducible results.

For each unyeasted dough there is a steady increase in amino-acid content with time, showing that flour contains proteolytic enzymes capable of decomposing flour proteins to the amino-acid stage and that proteolytic activity varies from flour to flour. In the yeasted dough the amino-acid content remains steady or increases slightly (to a less extent than in the unyeasted dough) for about an hour and then decreases, probably to a constant value. This is probably due to the utilisation of the amino-acid by the yeast organism as a source of nitrogen in its metabolism and prevents the direct comparison of the amino-acid production of yeasted and unyeasted flour doughs from revealing the effect of yeast proteases on flour proteins.

Table I. *The production of amino-acid in yeasted and unyeasted flour dough.*

Flour	Time (hours)	Amino-acid content mg. N per 2 g. flour	
		Without yeast	With yeast
1. A mill mixture	0	0.14	0.14
	1	0.17	0.14
	2	0.20	0.11
	3	0.25	0.06
	4	0.31	0.04
2. A mill mixture	0	0.17	0.17
	0.5	—	0.19
	1	0.20	0.18
	1.5	—	0.17
	2	0.23	—
	2.5	—	0.10
	4	0.29	—
	4.5	—	0.07
3. Manitoba	5	0.31	—
	0	0.22	0.22
	1	0.25	0.24
	2	0.28	0.18
	4	0.33	0.16
	5	—	0.16
	8	0.40	0.16
4. Low grade	0	0.35	0.35
	1	0.38	0.35
	2	0.42	0.33
	4	0.48	0.27
	5	0.50	0.26
	7.5	0.57	0.25
5. English	0	0.32	0.32
	1	0.36	0.34
	2	0.40	0.33
	4	0.45	0.20
	5	0.48	0.18

These results are not in agreement with those of Blagoveschenski and Yurgenson [1935], though the discrepancy may be partly explained by the technique and the quantities used, for it appears that these authors allowed the enzymes extracted from 0.25 g. of flour or yeast to act on the gluten from about 10 g. of flour, whereas in the present work the enzymes were allowed to act *in situ*. It is not certain that all the flour or yeast enzymes were extracted and indeed it may be suggested that the increase in amino-nitrogen of the control solutions of Blagoveschenski and Yurgenson [1935] is due to the action of flour enzymes which are not removed by washing but remain in the gluten which is used as the substrate for the controls.

To estimate the rate at which yeast utilises amino-acid, the conditions in the dough liquid were simulated in a solution which was analysed from time to time. The ratio of flour to water in a dough is approximately 2 : 1 and the ratio of flour to water for the extraction is 1 : 5 so that concentrations in the dough liquid are ten times those in the extract.

200 ml. of solution containing 1.4 g. of glutamic acid hydrochloride, 8 g. of sugar, 5 g. of salt and 8 g. of yeast were brought to  $p_H$  5.9 (the approximate  $p_H$  value of flour dough) by the addition of sodium hydroxide and incubated at 29°. At definite time intervals 5 ml. samples were taken, diluted to 50 ml. and centrifuged and the amino-acid content was determined as for the dough extract. In the titration to  $p_H$  8.0 before the addition of formalin, fading of the colour, due to the presence of carbon dioxide, was noted. When formalin is added the

solution becomes acid, so to avoid the possible loss of carbon dioxide from the acid solution the approximate amount of sodium hydroxide for the titration in the presence of formalin was added before adding the formalin.

It is recognised that the results of this experiment (Table II) must be applied with caution to the dough experiments. The amino-acid in the solution is more readily available both physically and chemically to the yeast, but the local concentration of amino-acid around the yeast cells in the dough may be higher than the bulk concentration. Because of this latter consideration the original concentration of amino-acid in the solution was made greater than had been found in the dough.

Table II. *Amino-acid content of a solution containing glutamic acid, sugar, salt and yeast.*

Time (hours)	pH	Amino-acid mg. N
0	5.90	0.67
1	—	0.60
2	—	0.48
4	—	0.39
6	4.68	0.36

From the quantities and dilutions used, Table II is directly comparable with Table I.

It is probable therefore that the consumption of amino-acid was greater in the solution than in the dough, yet the nitrogen used in 6 hours represents only 1.77 mg. of protein or approximately 1 % of the protein in a flour.

The effect of the yeast proteases on the flour proteins is left in doubt, but since in the solution only 0.28 mg. of amino-nitrogen has been used in 4 hours, of which about half would be formed by the action of the flour enzymes, it may be inferred that degradation of the proteins to the amino-acid stage by yeast is not serious, being about equal to the degradation caused by the flour enzymes.

#### SUMMARY.

1. In an unyeasted flour dough the amino-acid content increased steadily with time.
2. In a yeasted flour dough the amino-acid content increased slightly for about an hour and then decreased to an almost constant value.
3. The rate of utilisation of amino-acid by yeast in a solution similar to the dough liquid indicates that in a yeasted dough the protein is decomposed about twice as rapidly as in an unyeasted dough.

The author is indebted to the University of Western Australia for the award of a Hackett Research Studentship during the tenure of which this work was carried out; to the Director and staff of Rothamsted Experimental Station for placing at his disposal the facilities of the Station; and to the Research Association of British Flour Millers for the flours used in this work.

# CCLXXVII. THE DIFFERENTIAL EFFECT OF RADIUM RADIATION ON THE CARBOHYDRATE METABOLISM OF NORMAL AND TUMOUR TISSUES IRRADIATED AT LOW TEMPERATURE.

By HERBERT GRACE CRABTREE.

*From the Imperial Cancer Research Fund, London.*

*(Received August 28th, 1935.)*

THE action of short-wave radiation in affecting the rate of growth or causing the regression of an established tumour is a complex process which may be visualised in three phases.

1. The primary physical effects of atomic excitation, ionisation and disintegration, which induce physico-chemical and chemical changes.

2. The primary biological effects such as altered permeability of cell membranes or changes in the viscosity,  $p_H$ , state of protein aggregation and enzymic activity of the cell contents.

3. The final response of the affected tissues, both normal and cancerous, which is shown by visible changes in cell morphology and a general interaction between stroma and parenchyma.

The work reported here deals with the second phase only, namely with the changes induced in the enzymic activity of cells irradiated under different environmental conditions.

Many attempts have been made to attribute the action of radiation to its predominating effect on some single structure or physico-chemical equilibrium within the cell. Any such specific action seems improbable on general grounds, but it seems clear that damage to certain vital structures, with low powers of recovery, would lead to general impairment of cell function. In this sense it is possible to speak of selective damage to definite cell systems of paramount importance in cell economy.

With this conception in mind, the changes produced by radiation in the carbohydrate metabolism of tumour cells were examined [Crabtree, 1932]. It was thought possible that the abnormal metabolism of tumour cells might be related to their supposed greater vulnerability to radium. It was found that the two energy-yielding processes of respiration and glycolysis were not equally vulnerable to radiation. A selective diminution of respiration occurred whilst aerobic glycolysis remained relatively unimpaired. Though radiation affected two cell processes in a differential manner, no support was given to the idea that tumour cells were inherently more sensitive than normal cells.

This selective effect was utilised as a basis for a more extensive study of the possibility of influencing the vulnerability of tumour cells to radiation by varying the physiological condition of the respiratory system. In a series of papers [Crabtree and Cramer, 1934, 1, 2; Crabtree, 1934] it was shown that the radio-sensitive-ness of tumour cells was a function of the chemical condition of the iron-containing, oxygen-transporting factor of the respiratory system. With this factor in a reduced condition (either in free state in  $N_2$ -anaerobiosis or in partial

combination in CO-anaerobiosis) tumour cells were less radio-sensitive than when it was functioning aerobically. Conversely, when the iron, in oxidised condition, was "fixed" by HCN, tumour cells were more radio-sensitive. Any simple interference with the functional capacity of the glycolytic system, such as treatment with iodoacetic acid, sodium fluoride, variations in  $p_{\text{H}}$  or in glucose concentration, produced no detectable effects on the radio-sensitivity of the tissue. Tumour tissues suspended in phosphate media were more radio-sensitive than when suspended in bicarbonate media, a fact which was attributed to the damaging effect of phosphate media on their respiration. All these results supported the original finding that the vital and labile respiratory system was more vulnerable to radiation than the glycolytic system and played a dominant part in the biological response of irradiated tumour cells.

One result was obtained which was not explicable in terms of the above hypothesis. Tumour cells at low temperature were more radio-sensitive than at body temperature. The energy-supplying chemical systems are at a standstill at low temperature, and it is impossible to describe them in terms of functional condition. Yet one suggestive result was obtained. By irradiating tumour tissue under anaerobic conditions at low temperature, it was found that the effect of cold in increasing the radio-sensitiveness under aerobic conditions could be eliminated. This result conformed with the conception that the respiratory system was primarily concerned in the variations of sensitivity found.

The results summarised above were obtained in experiments where tumour tissues were irradiated *in vitro* under physiological conditions with known modifications and subsequently transplanted. The capacity for and rate of growth were the indicators used in assessing the effects of the treatment. This technique had the obvious limitation of being solely applicable to tumour tissue. It was decided to use a technique which was also applicable to normal tissues, and in particular to investigate the changes in metabolism induced by irradiation at low temperature. The results indicate that radiation produces a differential effect on the metabolism of normal and tumour tissues, which depends on the fact that tumour tissues have a characteristic high glycolysis.

The belief in a special vulnerability of tumour tissue to radiation has often been expressed in the literature of radiology. The basis of this belief was questionable, since a distinction was not drawn between the effects of radiation on tumour cells and on the tumour as a whole when in living association with its host. All the work carried out in this laboratory had supported the idea that normal and tumour cells were equally vulnerable. The present work shows that that conception was premature.

#### TECHNIQUE.

Previous experience had shown the essential importance of the time factor in experiments carried out *in vitro* with surviving material. Making allowance for variations in individual tissues, it was shown [Crabtree, 1932] that little effect on metabolism was detectable up to 6-7 hours of continuous  $\gamma$ -irradiation. This increased the difficulty of assessing results, since such time periods were of the same order as those during which surviving control tissues could be maintained in a condition of maximum functional activity. The only way to speed up the experiments was to use more intensive radiation and shorten the latent period as much as possible. The justification of this is given in the discussion. ( $\beta + \gamma$ )-Radiation from two radium applicators was used throughout this work. Each applicator, 23 mm. square, contained 110 mg. of  $\text{RaBr}_2 \cdot 2\text{H}_2\text{O}$ , the equivalent of Ra element being 58 mg. The lids of the applicators were of silver 0.12 mm. thick.

*Apparatus for irradiation.*

This is shown in Fig. 1. The tissue slices were placed in a cell built up with many layers of mica sealed together with a solution of celluloid in acetone.

The cell had a depth of 1.5 mm., and was shaped to allow an easy flow of the irrigating medium during irradiation. The tissue slices were held in position

Fig. 1. Apparatus for irradiation and irrigation of tissue slices.

by small cubes of boiled kidney, which were firmly gripped between the two halves of the apparatus when closed. The only obstacle between the unscreened applicators and the tissue slices was a thin sheet of mica *ca.* 0.015 mm. thick, and the liquid layer of medium 1.5 mm. deep. The central rectangular mica sheet containing the cell was fitted into a hollow outer sheet of brass, rectangular in shape and of the same thickness as the mica. This brass was soldered on to a lead plate 1.5 cm. thick containing a central circular hole to receive an applicator. The upper half of the apparatus was similar in construction, the mica portion having a flat surface which formed a lid to the cell. Suitable glass tubes sealed with wax in the upper lead plate and opposed to the two ends of the cell provided an inlet and outlet for the irrigating medium. Plasticene effected the final sealing of the applicator holders and the two halves of the apparatus, which were tightly gripped together with heavy screw-clips. The whole apparatus, thus sealed, was placed in water in a tank at the appropriate temperature, and the medium, after passing through a glass coil immersed in the tank water, was run through at a suitable rate. This ensured constancy of environmental conditions during irradiation, an important factor often neglected in work with radiation in the biological field. Non-irradiated controls were treated similarly in all experiments, and no adverse effect on these controls was ever detected. The times of irradiation were 3-7 hours.

*Metabolism measurements.*

These were carried out by standard methods. Generally ten bottles were used, five for the controls and five for the irradiated tissues.

Respiration, aerobic and anaerobic glycolysis were measured by Warburg's

method, and two additional measurements of respiration were made in phosphate-Ringer media. In the tables of results the original symbols introduced by Warburg for expressing the magnitude of respiration ( $Q_{O_2}$ ), aerobic glycolysis ( $Q_M^{O_2}$ ), anaerobic glycolysis ( $Q_M^{N_2}$ ) and total  $CO_2$  evolved ( $Q_{(O_2+N_2)}^{O_2}$ ), are used.

The last symbol is used only in Table III, which deals with normal tissues having a low aerobic glycolysis. The expression  $Q_{CO_2}^{O_2} - Q_{O_2} = Q_M^{O_2}$  shows the relationship of these magnitudes, assuming R.Q. unity.

## RESULTS.

*Irradiation of tumour tissue under aerobic conditions or in presence of M/600 HCN at 37.5°.*

The tumour mainly used was Jensen's rat sarcoma (J.R.S.), though a few experiments have been made with tumour strains growing in mice. The latter are

Table I. *Comparison of changes in the metabolism of tumour tissue irradiated under different conditions.*

1-6, in R.G.B. at 37.5° aerobically.

always unsatisfactory in work on tissue metabolism, since homogeneous slices of adequate size are difficult to obtain. All the results quoted in the Tables refer to experiments with J.R.S., though the mouse tumours behaved in a similar manner.

The irrigating medium was either Ringer-glucose-bicarbonate (R.G.B.) alone, or  $M/600$  HCN in R.G.B. The composition was described earlier [Crabtree, 1928], and the gas phase was 5%  $\text{CO}_2$  in oxygen. Table I contains some typical results and shows the times of irradiation and of the subsequent measurement of metabolism.

The general result confirms previous work. Tumour tissue under the influence of radiation at  $37.5^\circ$  suffers a selective diminution of its respiration during a period when its glycolysis, aerobic and anaerobic, is relatively unaffected. When the respiration is almost completely "fixed" with HCN, radiation produces a similar effect, but in considerably greater degree over corresponding periods of treatment. As was found by the transplantation technique described in the introduction, tumour cells treated with HCN and irradiated at body temperature are more vulnerable to radiation than when the respiration is functioning normally. No doubt other inhibitors of respiration would yield similar results, but since it is difficult to see any useful clinical application arising from this idea, this type of experiment has not been extended. Moreover the technique cannot be applied to normal tissues dependent for survival on respiration alone. The value of these experiments is in showing that the increased vulnerability of tumour cells with "fixed" respiration is made evident when two widely different criteria for assessing radiation effects are used, *viz.* transplantability in the animal after small exposures, and inhibition of metabolism *in vitro* after large exposures.

#### *Irradiation of tumour tissue at different temperatures.*

Table II contains a summary of typical results obtained. They have been selected at random.

The generalisation that irradiation at body temperature primarily affects respiration and irradiation at low temperature primarily affects glycolysis holds for every experiment carried out, the variations, considered quantitatively, being attributed to inherent variations in individual tissues. Such individual differences are more apparent when irradiation is carried out at body temperature and respiration is the point of attack. At low temperature there is greater uniformity of result; with a suitable dosage a clean-cut inhibition of glycolysis is possible whilst respiration is maintained unimpaired, the tumour tissue temporarily metabolising like a typical non-glycolysing tissue, *e.g.* liver.

One interesting point was noticed frequently. After irradiation at low temperature, metabolism measurements showed that anaerobic glycolysis was smaller than aerobic glycolysis. Using Warburg's two-bottle method for measuring respiration and aerobic glycolysis together, the accuracy of the calculated values of these two quantities depends upon their relative magnitude; a high glycolysis with a low respiration implies that the respiration may be inaccurately determined and *vice versa*. That the anomaly is not explicable on this basis is shown by the addition of HCN, which increases glycolysis to a figure somewhat greater than either the calculated aerobic glycolysis or the anaerobic glycolysis measured in nitrogen directly after irradiation. It is clear that the effect depends upon the power of recovery under different conditions; in oxygen this recovery is significant but not great; in nitrogen it is negligible.

Tumour slices have been irradiated at two intermediate temperatures (10° and 20°) with a view to finding the upper limit of the low temperature effect. At 10° the results are indistinguishable from those obtained at 0-4°. This may prove a useful practical consideration should the low temperature effect be utilised clinically. At 20° the effect is mixed, both the partially functioning respiration and glycolysis being inhibited. This observation may have a bearing on the conflicting results obtained by other workers who have measured the effects of radiation on metabolism.

If, instead of irradiating in the cold under aerobic conditions, HCN is added to the irrigating medium or  $N_2$  replaces  $O_2$ , no difference is found in the results obtained. Destruction of glycolysing power and maintenance of respiratory power are the invariable effects. Probably this reflects the limitations of the technique, as it contrasts with results already recorded in which the transplantability of tumour tissue was used to assess the effects of radiation. When dealing with artificially induced tissue degeneration, which only occurs after many hours of treatment, as in radiation experiments, differential effects can only be detected when they are of considerable magnitude. Evidently the relatively rapid damage to the glycolysing system at low temperature exceeds the attack on the respiratory system, whatever its condition, under the circumstances of these experiments.

Fig. 2 shows a graphical summary of all the results obtained by irradiating tumour tissue under different conditions. It does not represent a series of individual experiments, but a composite picture of the general nature of the differential effects observed.

Fig. 2. Effect of radium irradiation on the carbohydrate metabolism of tumour tissue surviving under different conditions.

*Irradiation of normal tissues at low temperature.*

It is impossible to apply the technique used for tumour tissues to normal tissues irradiated at body temperature. During the minimum latent period of 3–4 hours which elapses before radiation effects are detectable, normal control tissues at 37.5° degenerate too rapidly. At low temperatures this spontaneous degeneration does not occur. In Table III are collected typical results of experiments in which normal tissues were irradiated under conditions which produced a large or complete inhibition of glycolysis in tumour tissue. No significant effect on the respiration of any of these tissues was found. Any effects produced on the low glycolysis of some of the tissues used were not detectable with certainty, as they were within the margin of error of the technique employed.

## DISCUSSION.

Few workers have studied the effect of radiation on tumour metabolism, and the results recorded have been conflicting. Crabtree [1932] and Holmes [1933] have drawn attention to some of these but failed to reconcile the different findings. It is possible that the results recorded here offer a partial explanation. Many workers with radiation in the biological field concentrate upon accuracy of dosage and do not clearly define the environmental conditions of their material during irradiation. Since the dosages required to obtain a certain result, *e.g.* inhibition of the capacity for growth on transplantation, may vary by 100 % according to the external conditions during irradiation, it is clear that the latter are of equal importance in obtaining significant results.

Two criticisms may be directed against this work, *viz.* that the results have been attained with enormous doses of ( $\beta + \gamma$ )-radiation, and that the experimental conditions, when compared with those found clinically, are too simple. In answer, it may be pointed out that when surviving tissues are irradiated *in vitro* the effects produced are the same for ( $\beta + \gamma$ )- as for  $\gamma$ -radiation, when the smaller intensity of  $\gamma$ -radiation is compensated by a longer period of treatment. Experiments on metabolic changes, transplantability and regression of tumours in the animal all support this view. In clinical work  $\gamma$ -radiation and X-rays are obligatory on account of their greater penetrating powers and the greater ease of obtaining more uniform dosage. In the experiments described here the maximum intensity of radiation available was deliberately used in order to shorten the experimental period and prevent adverse effects on surviving control tissues, which might confuse the results.

That the effects described are not entirely dependent on the large doses used is suggested by two facts.

1. A few experiments were carried out using  $\gamma$ -radiation only and slightly increasing the time of irradiation. The same type of effect was produced but to a lesser degree. The technique used only permits reactions to be followed over a limited time, but it is probable that once reactions are initiated, provided the dose applied has been sufficient to prevent reversibility, they proceed to the same end-point in a time which is a function of the dose.

2. The results of the metabolism experiments, where they are reproducible at all, run parallel with the results of the transplantation experiments. In the latter case comparatively small doses were used (30–40 min. of ( $\beta + \gamma$ )-, 3–4 hours of  $\gamma$ -radiation alone). This again suggests that large and small doses initiate processes which are similar in type, the size of the dose only determining the time before the end-effect is reached.

The hypothesis put forward in earlier communications, that the functional condition of the respiratory system determines the response of living cells to radiation and that the glycolytic mechanism is not primarily concerned, is only true when irradiation is carried out at body temperature. Respiration is a process common to all mammalian tissues; to attempt to make a differential attack on normal and tumour tissues by modifying this process did not promise anything of clinical value.

High aerobic glycolysis differentiates pathological overgrowths from almost all normal tissues. Irradiation at low temperatures might provide a method of using this difference to damage the tumour cell selectively by inhibiting its secondary mechanism for obtaining energy. Glycolysis in tumour cells is probably helpful in aiding their survival under conditions of restricted oxygen supply. A badly vascularised tumour, where regions in a state of partial anaerobiosis must exist, is notably insensitive to radiation applied at ordinary conditions of temperature. It is suggested that irradiation at low temperature might make such a tumour more sensitive by selectively damaging its glycolytic mechanism.

Whether irradiation at low temperature can be used to enhance the damage to tumour cells with a concomitant sparing of adjacent normal tissues in clinical cases remains to be proven. Experiments to test this conception are in progress.

Mottram [1924] recorded a relatively increased skin reaction after exposure to radiation at low temperature. This enhanced effect on normal tissues is not incompatible with the results recorded here. In Mottram's work the reactions of normal skin at different temperatures were compared. This work contrasts the reactions of normal and tumour tissues under the same condition of low temperature and shows a differential effect which is favourable to the normal tissue.

#### SUMMARY AND CONCLUSIONS.

1. The effect of radium radiation on the carbohydrate metabolism of normal and tumour tissues, irradiated *in vitro* under different environmental conditions, has been studied.
2. "Fixing" the respiration of tumour tissue with HCN at 37.5° makes it more sensitive to radiation.
3. Irradiation of tumour tissue at body temperature, either under aerobic or anaerobic conditions or with HCN present, causes a selective lowering of respiration whilst glycolysis remains relatively unaffected. The effects produced vary in degree, but are similar in character; respiration is primarily damaged at this temperature.
4. Irradiation of tumour tissue at low temperature (0–10°), either under aerobic or anaerobic conditions or with HCN present, causes a selective lowering of glycolysis, whilst respiration remains relatively unaffected. This selective damaging of glycolysis is much more pronounced than the converse effect on respiration at body temperature. It is possible to effect a clean-cut elimination of tumour glycolysis, leaving respiration intact.
5. Irradiation of normal tissues (spleen, liver, kidney, testis) at low temperature, under identical conditions of time and environment, produces little (or no) effect on their metabolism, since their respiration is not accompanied by aerobic glycolysis.
6. This differential damaging of tumour cells at low temperature by way of their characteristic glycolytic process may be of clinical value.

# CCLXXVIII. THE BASIC AMINO-ACIDS OF TYPICAL FORAGE GRASS PROTEINS.

By ERNEST JOHN MILLER.

*From the Biochemical Department, Imperial College of Science and Technology,  
South Kensington, S.W.7.*

*(Received August 28th, 1935.)*

THE need for accurate information as to the quantities of amino-acids yielded on acid hydrolysis by proteins derived from green forage crops requires no emphasis in view of their value to the animal as food. Particularly important are arginine, histidine and lysine, the last being one of the two indispensable amino-acids which the animal body apparently cannot synthesise. This is especially exemplified in milk production from cows, for, the milk proteins being relatively rich in lysine, the milk yields will be low if insufficient of this amino-acid be present in the pasturage [cf. Morris and Wright, 1933, 1, 2].

In the present research the proteins from a number of typical forage grasses (including red clover) have been analysed for the basic amino-acids by methods which involve their actual individual isolation and which can therefore be expected to give reliable results. Estimation by the Van Slyke procedure, which depends mainly on the amount of nitrogen precipitated by phosphotungstic acid under controlled conditions, has been explored and found to give values for these proteins which can only be regarded as extravagant.

## EXPERIMENTAL.

The preparation of the proteins used in the present work has already been described [Miller and Chibnall, 1932; Chibnall *et al.*, 1933].

### *Large scale analysis of the basic amino-acids of cocksfoot protein.*

The method adopted was that of Vickery and his co-workers [cf. Vickery and Shore, 1932].

88.7 g. of dry protein (N, 13.9 %, ash-free) prepared from samples of cocksfoot cut in the spring of 1932 were used. The general procedure has been given in the above-mentioned and preceding papers [especially Vickery and Leavenworth, 1928], but since it has been varied from time to time in certain details it may be stated here that the following reagents were used in the present work:

1. Hydrochloric acid in the initial hydrolysis.
2. Silver oxide throughout, both for the introduction of excess silver ion and for the removal of chlorides.
3. Hydrogen sulphide to remove silver.
4. Kahlbaum's cupric hydroxide to precipitate cystine (present only in small amount in the grass proteins).
5. Kahlbaum's phosphotungstic acid for the precipitation of lysine.

The results are shown in Table I.

As a check on the total bases estimated by this and the Block procedure detailed below, a determination of total basic N by the usual method of Hausmann was also made, using again Kahlbaum's phosphotungstic acid.

Table I. *Large scale analysis of cocksfoot protein.*

	Expressed as N in % protein-N	Expressed as % of protein (N = 16.0 %)	% of S in flavianates and explosion points of picates	
			Found	Theory
Arginine	13.6*	6.40	6.50	6.56
Histidine	1.66	0.93	8.23	8.17
Lysine	5.27	4.11	1st crop 267° 2nd and 3rd crops 260°	266-267°
Total bases	20.53	11.44		
Total bases (Hausmann)	20.0			

\* This figure includes a solubility correction for the silver salt of arginine; if this correction be excluded the figure would be 12.70%.

*Small scale analysis of the basic amino-acids of various proteins.*

The method was essentially the very convenient application of the above large scale analysis to small quantities of proteins, devised by Block [1934]. His procedure was adhered to, but in addition, from the present author's experience, the following comments are worth recording.

In the initial removal of sulphuric acid as barium sulphate it was considered safer, in view of the bulkiness of the precipitate, to give it more than one washing with boiling water, especially in the case of proteins such as those from grasses, which give rise on hydrolysis to a considerable amount of humin.

*Histidine.* In the precipitation of histidine as its silver salt, it is more accurate and takes little longer after experience has been gained to follow the large scale analysis in the adjustment of the reaction to  $p_H$  7.2, *viz.* withdrawing 2 ml. samples from the supernatant liquid after the precipitate has settled, mixing with 2-3 drops of bromothymol blue and comparing with 2 ml. of a buffer solution of  $p_H$  7.2 with the same amount of indicator.

*Lysine.* Block recommends that the strongly alkaline filtrate from the precipitated arginine silver should be made acid to  $p_H$  1 to remove barium. The present author has sometimes found it necessary to make more acid than this to ensure the removal of all barium, owing to the presence of a considerable amount of nitric acid. As Block implies it is advisable to precipitate the silver as sulphide before removing the barium sulphate precipitate, as the combined precipitates can then be washed more easily and with less chance of formation of colloidal solutions; if these do form they can be cleared by the addition of a drop or two of 20% sulphuric acid. Two washings were given. The resulting filtrate and washings should on no account be reduced in volume below 5 ml. otherwise the concentration of the nitric acid will bring about decomposition of the lysine.

Kahlbaum's phosphotungstic acid was used to precipitate the lysine. The lysine phosphotungstate should not be exposed to a high temperature for longer than is necessary, owing to the possibility of decomposition. For a similar reason, the solution, after the addition of the 5 g. of barium hydroxide, should not be heated for more than a few minutes at 90°. If decomposition has taken place at this or any previous stage it will be shown by the development of a yellow colour in the solution, either at once or after the addition of barium carbonate and subsequent concentration of the solution. This will result in the separation of a brown oil on adding alcohol to the concentrated lysine carbonate solution. If for any of the above reasons the lysine estimation be vitiated, the experiment can be repeated on another sample of protein without the necessity of precipitating arginine and histidine separately; they can be removed together as their silver salts at  $p_H$  14. Results of the analysis are given in Table II, and when comparing them with those given in Table I it is to be remembered that no correction for the solubility of arginine silver has been applied.

Of the two methods described above that due to Vickery takes the longest time but would appear to be the most reliable and accurate. From Table I it will be seen that the flavianates analyse for sulphur to within less than 1% of the

Table II. *Small scale analysis of various proteins.*

\* Fraction lost.

theoretical. The one possible source of error is in the correction for the solubility of the silver salt of arginine. This is of considerable magnitude, amounting to more than 6.5 %, and obviously cannot be fixed with any accuracy since the solubility will vary with the nature and quantity of the other amino-acids present.

The Block application of the above method is much more rapid and can be carried out on much smaller amounts of protein, but the time saving is mainly effected by decreasing the number of silver precipitations, for instance, giving only one histidine precipitation at  $p_H$  7.2 instead of the two which Vickery and Leavenworth [1928] hold to be necessary in order to avoid arginine contamination in the final histidine fraction. Moreover Block takes out the histidine silver precipitate from a solution containing all the other products of protein hydrolysis, instead of taking out an initial silver precipitate at  $p_H$  13-14 containing both arginine and histidine and separating these subsequently. At any rate in the series of Block analyses given in Table II the present author has found that both the arginine and histidine flavianates show sulphur contents varying from 2.5 to 8 % higher than the theoretical. Otherwise the agreement between the one large scale analysis (Table I) and the corresponding small scale analysis (Table II) is fairly close, the latter being a little lower in arginine and a little higher in histidine. This seems to point to arginine contamination in the histidine fraction, but this may not necessarily be so since the sulphur content of the histidine diflavanate is high. Moreover none of the characteristic orange-coloured arginine flavanate could be detected in the yellow histidine diflavanates. It is possible then that the high sulphur percentage is accounted for by slight contamination with flavianic acid itself, presumably due to the very small volumes of solutions used.

It will also be apparent from Table II that the yields of total bases by isolation fall short of the Hausmann figures by some 6-18 %, but part of this difference is accounted for because in the Block (and also the Vickery) method the figures given for lysine (isolated as picrate) represent yields of 69-77 % of the nitrogen in the fraction precipitated by phosphotungstic acid. If this residual nitrogen, presumably mainly non-lysine-N, is taken into account, the difference between the Hausmann figures and those obtained by isolation is reduced to 1-8 %. Taken as a whole, the results given in Tables I and II compare favourably with those quoted by Osborne [1924] for a large number of seed proteins analysed by the Hausmann and the older Kossel methods respectively.

*Van Slyke analysis of the basic amino-acids of cocksfoot protein.*

As has already been mentioned the total basic N calculated from the yields of the isolated bases is very close to that obtained by simple precipitation with phosphotungstic acid according to the procedure of Hausmann, but is considerably lower than the value (27.9 %) obtained by Miller and Chibnall [1932] from a different sample of cocksfoot protein analysed by the method of Van Slyke. Since a sample of the protein used in the two former determinations was not available another sample containing 13.7 % N was analysed by the latter method, and the total basic N (28.8 %, uncorrected for solubility of bases, as shown in Table III) was even higher than that found by Miller and Chibnall.

\* The cystine-N of this protein is about 0.15 %.

Reference to the results of analyses of numerous seed proteins by the Kossel and Hausmann methods quoted by Osborne [1924] and the corresponding data for Van Slyke analyses collected by Larmour [1928] shows that discrepancies of this order, viz. 6–8 units in the percentage of basic N, are fairly general between the direct and indirect methods of analysis. In all cases the difference is accounted for almost entirely by enhanced values for histidine-N and lysine-N. Attention has occasionally been drawn to this point by previous workers, but the only constructive criticism so far advanced has been that of Gortner and Sandstrom [1925] who point out the possible interference of proline in the Van Slyke analysis. One important difference however in the respective procedures of Hausmann, Kossel, Vickery and Block on the one hand and of Van Slyke on the other hand seems to have passed unnoticed, namely, that in the former the precipitation of the bases with phosphotungstic acid is made in the presence of sulphuric acid, whilst in the latter it is made in the presence of hydrochloric acid. To find out if the change of mineral acid was indeed the cause of the discrepancy, the following experiment was carried out with a sample of the cocksfoot protein used in the second Van Slyke analysis.

*Determination of N precipitated by phosphotungstic acid under Hausmann and under Van Slyke conditions.*

4.09 g. of protein, containing 0.557 g. of N, were hydrolysed by boiling under reflux with 120 ml. of 20 % hydrochloric acid for 16 hours. The solution was evaporated to dryness *in vacuo* at 45° to remove free hydrochloric acid, the residual syrup taken up in 300 ml. of water, and 45 ml. of a 17 % aqueous suspension of magnesium oxide were added. Ammonia and humin were removed in the usual way and the amino-acid filtrate was reduced in volume to 100 ml. to provide four equal portions for the following experiments.

1. Two portions were treated according to Van Slyke's procedure as follows. Each portion was diluted to about 40 ml. and treated with 6 ml. of concentrated HCl and 5 g. of Kahlbaum's phosphotungstic acid dissolved in a little water. The mixture was diluted to about 67 ml., heated on a boiling water-bath until the precipitate had practically all dissolved and kept for 46 hours at room temperature. The recrystallised phosphotungstates were filtered off on a 5 cm. Büchner funnel through a hardened filter-paper and washed, without interrupting suction, with 17 ml. of the usual wash-liquid (2.5% phosphotungstic acid in 3.5% HCl) in portions of 4–5 ml. at a time. The whole of the precipitate was dissolved in *N* NaOH and submitted to Kjeldahl analysis.

2. The remaining two portions were each diluted to 100 ml. and treated with 5 g. of concentrated  $H_2SO_4$  and 30 ml. of 20% phosphotungstic acid in 5%  $H_2SO_4$ . The mixture was left for 22 hours at room temperature, centrifuged and the precipitate washed with 200 ml. of 2.5% phosphotungstic acid in 5%  $H_2SO_4$  in three successive portions of 60–70 ml. each. The final centrifuged precipitate was analysed for total N as before.

In 1 (Van Slyke conditions) the duplicate results for total basic N were 29.4 and 29.8% of the protein-N, whilst in 2 (Hausmann conditions) the corresponding figures were 22.4 and 22.4% respectively. The experiment demonstrates quite clearly that the greatly enhanced values for total basic N obtained by the Van Slyke method are due to the employment of hydrochloric acid at this stage. The nature of this excess basic N is already being investigated in this laboratory, for clearly the present findings cast doubt on the validity of the whole Van Slyke procedure and of the numerous analyses of proteins and foodstuffs which have been made by means of it during the past 20 years.

*The basic amino-acids of pasture proteins.*

From Tables I and II it will be apparent that the proteins from the various forage grasses, including red clover, differ very little in their contents of basic amino-acids in spite of their variations in total N (12.8–15.0%), confirming the view already expressed [Miller and Chibnall, 1932; Chibnall *et al.*, 1933] that the N-free material always present to some extent in these preparations is merely an adulterant, and that the leaf protein as a whole, though differing somewhat in each individual case, must be, if not a chemical entity, at least a mixture of proteins of very similar constitution.

In the two papers referred to immediately above evidence was given that the samples of protein, obtained in yields of from 10 to 30%, could be taken as representative of the whole leaf protein. Since the basic amino-acids probably undergo little, if any, decomposition during the hydrolysis of a protein in the presence of much carbohydrate material, opportunity has been given to test this supposition in the following way.

A supply of freshly cut spring pasturage of good agricultural quality, consisting chiefly of perennial rye grass, was obtained from Jealotts Hill on the 22nd of May, 1935. The dry weight was 22% and the total nitrogen 2.63% of the dry weight. 8 kg. of the fresh grass were treated by the method of Chibnall *et al.* [1933] and 52.7 g. of protein (N, 12.1%, ash-free) were obtained, representing a yield of 17.4% of the total leaf protein.

The remainder of the fresh grass was dried rapidly (1–2 hours) in a steam-oven through which a slow current of air was drawn and then ground to a fairly fine powder in a small mincing machine. 29.2 g. of this material (dry weight, 26.9 g.) were exhaustively extracted with ether in a Soxhlet apparatus to remove fatty substances, chlorophyll *etc.* and the residue was treated twice successively

with 300 ml. of the following solvents at the boiling-points (to remove all non-protein nitrogenous substances), *viz.* 95 % alcohol, 50 % alcohol and water; 20 % of the total leaf-nitrogen was removed in this way. The final protein-rich residue was only faintly straw-coloured. Previous experience had shown that the protein was best extracted from this residue by the use of 4 % HCl; accordingly 13.5 g. of the dry residue, containing 0.45 g. N, were extracted with 450 ml. of 4 % HCl by boiling under reflux for 48 hours. After cooling and filtering, the dried residue weighed 5.34 g. and contained 0.053 g. N, whilst the filtrate and washings contained 0.373 g. N; 88 % of the total protein-N had therefore been extracted. This yield compares very favourably with the previously mentioned 17.4 % for the isolated protein. On the other hand the latter contained 12.1 % of N, whereas the protein extract contained solid material amounting by difference (13.5-5.34) to 8.16 g. with a nitrogen content of 0.373 g. or only 4.7 %.

The 4 % HCl extract mentioned above was evaporated to dryness under reduced pressure at 45°, the residue dissolved in water and the solution again concentrated to remove most of the free HCl. The residual syrup was dissolved in 40 ml. of water, an equal volume of concentrated HCl was added, the whole boiled under reflux overnight (16 hours) and the solution freed from HCl by evaporation *in vacuo* as described above. The final syrup was dissolved in water, the humin filtered off, washed and submitted to Kjeldahl analysis. It contained 2.65 % of the nitrogen in the initial 4 % HCl solution. The filtrate and washings (volume approx. 200 ml.) were treated with 1 ml. of concentrated H<sub>2</sub>SO<sub>4</sub> and then with a suspension of silver oxide until free from chlorine. The precipitate was centrifuged and washed twice with 200 ml. of boiling water containing 1 ml. of concentrated HCl and finally with boiling water alone. The combined washings were again freed from chloride with silver sulphate (as no silver oxide was available), the silver chloride filtered off and washed once. Both these precipitates of silver chloride will probably contain a small amount of histidine silver which cannot be removed very readily in such a small scale experiment; it is to be expected therefore that the ultimate value for histidine-N obtained later will be slightly low. The combined filtrates were concentrated to 50 ml. and warm barium hydroxide solution was added carefully to  $p_H$  not > 4. The precipitate of barium sulphate was centrifuged and washed and the filtrate and washings were concentrated to 25 ml. At this stage the Block procedure described above was applied.

The results of the analysis are given in Table IV, together with that of the isolated protein. It will be seen that in spite of the relative large difference

Table IV. *Comparison of the basic amino-acids of the isolated protein and of the protein extracted by 4% hydrochloric acid from spring pasturage.*

	Expressed as N in % of protein-N			
	Arginine	Histidine	Lysine	Total base
Isolated protein	11.0	2.22	5.05	18.27
Protein extracted by 4 % hydrochloric acid	10.2	1.42	5.89	17.51

between the yields (88 % as against 17.4 %) in which the proteins had been prepared, the distributions of hexone bases are similar in both cases, confirming the view expressed above that these isolated proteins, although obtained from grasses in yields not exceeding 30 %, may be taken as representative of the whole protein of the leaf.

## SUMMARY.

The proteins from a number of typical forage grasses (including red clover) have been analysed for the basic amino-acids by individual isolation of the latter. One large scale analysis of a cocksfoot protein showed the following yields (expressed as N in % of protein-N): arginine, 13.6; histidine, 1.66; lysine, 5.27. Small scale analyses of the proteins from other grasses gave: arginine, 12.1-13.1; histidine, 1.9-2.7; lysine, 4.4-5.3. A protein extract obtained from a sample of mixed pasture grass gave similar values.

A Van Slyke analysis of a cocksfoot protein indicated: arginine, 13.6; histidine, 7.1; lysine, 8.1. Reasons for these large figures are suggested and the method criticised.

Grateful acknowledgment is made to Prof. A. C. Chibnall for much help and advice. The cost of this research has been defrayed by a grant from Imperial Chemical Industries, Ltd.

# CCLXXIX. THE X-RAY INTERPRETATION OF DENATURATION AND THE STRUCTURE OF THE SEED GLOBULINS.

BY WILLIAM THOMAS ASTBURY AND SYLVIA DICKINSON

(*Textile Physics Laboratory, University of Leeds*)

AND KENNETH BAILEY<sup>1</sup>

(*Biochemical Department, Imperial College of Science and Technology, South Kensington, S.W. 7*).

(*Received August 29th, 1935.*)

THE X-ray diffraction photographs usually obtained from apparently non-fibrous proteins have so much in common with one another and with the photographs given by certain natural protein fibres when disoriented that the inference seems clear that all proteins at some stage of their existence are fibrous in the molecular sense [Astbury, 1933; 1934, 1, 2]. Recently [Astbury and Lomax, 1934, 1, 2; 1935] this concept has been expressed as a generalised interpretation of denaturation in the conclusion that the two more stable and insoluble states of protein structure, the fibrous and the denatured, are based on fundamentally similar modes of molecular arrangement; that, in fact, the denatured state<sup>2</sup> is essentially a fibrous state inasmuch as it always consists of peptide chains, often fully extended, and aggregated after coagulation in parallel bundles, as in fibroin [Meyer and Mark, 1928],  $\beta$ -keratin [Astbury and Street, 1931; Astbury and Woods, 1933],  $\beta$ -myosin [Astbury and Dickinson, 1935], fibrin [Katz and De Rooy, 1933] *etc.* It was found that heat-denaturation of the albumins, for instance, merely makes the X-ray photograph more like that of a random arrangement of fibres of  $\beta$ -keratin (stretched hair, horn, *etc.*; *cf.* Plate V, Figs. 1 and 3).  $\beta$ -Keratin is built from almost fully-extended polypeptide chains linked side-to-side, firstly by combinations between their side-chains ("side-chain linkage"), and secondly in a direction at right angles [Astbury and Sisson, 1935], through attractions between the  $-\text{CO}$  and  $-\text{NH}$  groups of neighbouring main-chains ("backbone linkage"). The three-dimensional structure is that of a pile of polypeptide "grids", the average distance apart of the main-chains in the plane of each grid being about 9.8 Å. ("side-chain spacing") and the distance between the grids being 4.65 Å. ("backbone spacing"). These two spacings correspond respectively to the two reflections, 001 and 200, seen on the equator of Fig. 4: they are the two principal side-spacings of the  $\beta$ -keratin crystallites, whilst the reflection 020 (spacing about 3.4 Å.) gives the average length of an amino-acid residue in the direction of the main-chains. Fig. 4 is a "fibre photograph" of crystallites all pointing roughly in the same direction (the fibre-axis) and taken with the X-ray beam perpendicular to this direction; but when the crystallites are

<sup>1</sup> Beit Scientific Research Fellow.

<sup>2</sup> The seed globulins, at least, appear to pass through an intermediate fibrous state before reaching complete denaturation. It is possibly better therefore to reserve the word "denatured" for the final fibrous state analogous to  $\beta$ -keratin, and to describe intermediate states as "degenerate" (see below).

disoriented the result is very like (though not strictly identical with) Fig. 1, which is an X-ray view along the fibre-axis of stretched horn.

The disoriented photograph of  $\beta$ -keratin thus appears mainly as two more prominent rings, the inner corresponding to the side-chain spacing and the outer to the backbone spacing, and a less prominent ring arising mostly from the "diagonal reflection" 210 (spacing about 3.7 Å.) but partly also from the "meridian reflection" 020 (spacing about 3.4 Å.); and this is just the kind of photograph that is typical of a coagulated denatured protein [Astbury and Lomax, 1934, 1, 2: 1935], as is shown clearly by reference to Fig. 3, the photograph of boiled egg-white dried in the air.<sup>1</sup> Practically all proteins so far examined by X-rays under ordinary conditions give either a photograph of a similar kind or one structurally related to it [*cf.* also Katz, 1934], and it is a reasonable enough inference that most proteins as commonly available for X-ray examination are either degenerate or completely denatured.

Svedberg's [1930] derivation with the ultracentrifuge of the molecular weight and globular form of many proteins in solution suggests such an inference, but the question has recently been settled crystallographically by the work of Bernal and Crowfoot [1934] and Crowfoot [1935] on the structure of unaltered crystalline pepsin and insulin. Large crystal spacings have also been observed by Clark and Corrigan [1932], Fankuchen [1934] and Wyckoff and Corey [1935], but Bernal and Crowfoot have been able to carry the X-ray analysis sufficiently far to show geometrically that the molecules in both crystalline pepsin and insulin are indeed very much of the shape (roughly spherical) and weight (34,500) deduced by Svedberg [1931] and his collaborators [Sjögren and Svedberg, 1931; Philpot and Eriksson-Quensel, 1933]. Even single crystals of pepsin,<sup>2</sup> however, give the usual powder photograph of the type just described, once they have been allowed to dry [Astbury and Lomax, 1934, 1]. Obviously then, most so-called crystalline proteins are only pseudomorphs after degeneration or denaturation: the molecules tend towards "cannibalism", so to speak, and their complex structure is frequently so precariously balanced, because it is so complex and so rich in charged centres, that they may have to be protected even from one another. This is the reason why protein crystals, for stability, generally require such a high water content, or to be kept in some specific mother-liquor. On dehydration or raising the temperature, for instance, one can imagine active side-chains reaching out to their neighbours, upsetting the balance of the whole system and leaving finally only the débris of the original special configuration. X-rays indicate that this débris, whether produced by disintegration or by unidirectional rearrangement, consists simply of peptide chains.

So far the argument has been indirect: it has been based on the study of protein "powder photographs" in relation to the "fibre photographs" of macroscopic fibres such as  $\beta$ -keratin, which is now known beyond reasonable doubt to be constructed out of parallel bundles of fully-extended polypeptide chains. Clearly then, if it is sound, it should be possible to make (probably elastic) macroscopic fibres even out of a "globular" protein, once it has been denatured. If polypeptide chains are there, but in random orientation, it should be possible to draw them into parallel alignment and so to obtain, not merely a powder photograph resembling that of disoriented  $\beta$ -keratin (Fig. 1)—which, after all, still does not constitute an incontrovertible proof of similarity, in spite

<sup>1</sup> An almost identical photograph is given by serum albumin, denatured and coagulated by gently heating an aqueous solution [Astbury and Lomax, 1935].

<sup>2</sup> From the same source as those of Philpot and Eriksson-Quensel and of Bernal and Crowfoot [Northrop, 1930].

of the strong support afforded by hydration studies [Astbury and Lomax, 1935]—but a genuine fibre photograph analogous to that of oriented  $\beta$ -keratin (Fig. 4). Such an experiment, if successful, would provide a wholly satisfactory demonstration for the protein under examination—and thence, by implication, for proteins in general—that the denatured state is indeed a fibrous state arising out of the liberation or spontaneous generation of peptide chains.

*Denatured fibres and films.*

The vegetable globulins edestin [Svedberg and Stamm, 1929], excelsin and amandin [Svedberg and Sjögren, 1930], legumin [Sjögren and Svedberg, 1930] and pomelin [Krejci and Svedberg, 1934] have been examined with the ultra-centrifuge and found to constitute a group of molecular weight about  $6 \times 34,500$  and molecular shape not far removed from the spherical. Edestin is thus a typical "globular" protein, very definitely crystalline, which should serve admirably for the X-ray test of denaturation just proposed.

In the first experiments edestin was denatured by dissolving in aqueous urea, and fibres were prepared by squirting the viscous solution so formed (8% protein and 43.5% urea) into water, or water containing 0.5% NaCl, at various temperatures up to about 55°. The fibres were then stretched in water or in the salt solution at temperatures up to about 70°. All showed striking, largely reversible, long-range elasticity, the extensibility increasing with the temperature of stretching up to something of the order of 700% at 70°. Those squirted and stretched at ordinary temperatures could be extended in water to just over twice their initial length and quickly recovered almost completely when released, whilst others stretched at higher temperatures extended further but showed only imperfect recovery. X-ray examination of these various types of fibre was hardly as profitable as had been hoped, but at least it drew attention once more to the part played by temperature in the alignment process (*cf.* rubber) and emphasised the point that denaturation does not necessarily proceed by a single stage (see below). At least two kinds of incipient fibre photograph were obtained, but nothing so definite as those shown in Figs. 4 and 5. The experiments were not for the time being carried further, partly owing to the tedium of preparing parallel fibre bundles sufficiently large for X-ray examination and partly on account of the simplicity with which it was found that films could be made.

Denatured edestin films were made by two methods, similar in principle to those used for the preparation of myosin films [Astbury and Dickinson, 1935]. In the first the urea solution mentioned above was poured evenly over a glass slide which was then gently inserted into water until the protein was deposited as a thin layer. This was then left in water for about half an hour, allowed to dry, and the process repeated several times in order to build up a deposit of suitable thickness, which was finally re-wetted and peeled off. Several superposed thicknesses were then compressed between pieces of plate glass, and the resulting film was allowed to become almost dry and cut into strips.

In the second method an aqueous solution containing 4% protein and 10%  $\text{CaCl}_2$  was poured on to a glass plate, allowed to dry, washed for about 10 min. and drained. As before, the process was repeated several times and the accumulated layer peeled off wet and washed overnight in running water. A number of superposed layers were then compressed between plate glass to about one third their initial thickness and cut into strips.

The urea films gave extensions of 200–250% at about 40° and contracted when released in water to a residual extension of the order of 100%, whilst one calcium chloride film gave an extension of 280% with a similar residual extension

on release. On the whole, the calcium chloride films gave better-defined X-ray photographs, the urea films, like the corresponding fibres, sometimes showing besides traces of a second fibre photograph. Fig. 2 is a "powder photograph" of unstretched denatured edestin prepared from urea solution (*cf.* Figs. 1 and 3), and Fig. 5 is a "fibre photograph" of the film from calcium chloride solution which was stretched to an extension of 280% (*cf.* Fig. 4). There can be no doubt of the success of the experiment and of the configurational analogy between stretched denatured edestin and  $\beta$ -keratin. The side-chain spacing for denatured edestin is about 10 Å., the backbone spacing about 4.5 Å., the diagonal spacing about 3.7 Å., and the meridian spacing about 3.3 Å. (*cf.*  $\beta$ -keratin, above).

Preliminary experiments of a similar nature were carried out with excelsin also, but so far it has not been found possible to obtain a photograph strictly comparable with Figs. 4 and 5. Both elastic fibres and films were prepared as described above, but only imperfect orientation was attained even in a film (made from calcium chloride solution) stretched by 330%. The photographs obtained however were certainly crude "fibre photographs" of peptide chains, with the side-chain reflection and the backbone reflection both converging on the equator as in Figs. 4 and 5; but there was always present another reflection of spacing about 6 Å. A photograph of this type had already been found with edestin fibres spun from urea solution and stretched by 270%, and a similar photograph was obtained again later with a stretched film of denatured egg albumin prepared from urea solution (see below); but pending further investigation it will be more convenient at the present stage to suspend judgment as to its more exact interpretation.

The most interesting result was obtained with the X-ray examination of "poached" films of egg-white. Svedberg [1930] showed that the egg albumin molecule in the ultracentrifuge is practically spherical and of weight 34,500, and in view of the strong resemblance between Figs. 2 and 3 an enquiry into the effect of stretching the denatured protein was obviously indicated. Films of egg-white were poached for about a quarter of an hour at the bottom of a small covered beaker standing in boiling water, allowed to dry and then cut into strips. Some of these strips, if not re-wetted too much, were found to stretch to twice their initial length or more, and to give when stretched X-ray photographs such as that shown in Fig. 6. The striking—and, it must be confessed, unexpected—feature of this photograph is that the backbone reflection lies, not on the equator, but on the meridian. The side-chain reflection lies on the equator, as in Figs. 4 and 5, but in the original negative there can be seen also a vague outer equatorial reflection apparently corresponding to the amino-acid spacing; that is to say, 020 and 200 have changed places. The interpretation of this interchange between backbone and amino-acid spacing must mean that the peptide chains in denatured egg-white are relatively so short that the average length of the crystallites in the direction of the main-chains is shorter than their thickness in the direction of the backbone spacing; in other words, whereas the chain-bundles in  $\beta$ -keratin and denatured edestin are much longer than they are thick, those in denatured egg-white are actually shorter than they are thick. Fig. 7 illustrates the point. *A* represents, purely diagrammatically, a crystallite formed by the parallel alignment of long peptide chains, whilst *B* represents a corresponding crystallite built from short chains. In both the amino-acid spacing is in the direction of the main-chains of course and the latter are linked side-to-side by side-chain linkages (shown) and backbone linkage (not shown) at right angles. The chain-bundles so formed are thinnest in the direction of the side-chains [Astbury and Sisson, 1935] and lie normally along the natural fibre-axis or the axis of stretching.

If however it should happen that the main-chains are shorter than the width of the bundles in the direction of the backbone spacing (the side-chain dimension is apparently always short), the act of stretching will tend now to bring the backbone spacing parallel with the axis of extension and leave on the equator not merely the side-chain reflection, which is usual, but also the reflection corresponding to the length of the amino-acid residues. This is what happens when denatured egg-white is stretched: but the difference between chain-length and the thickness of the crystallites in the direction of the backbone spacing cannot be very great, otherwise short arcs or spots would be obtained instead of the comparatively long arcs shown in Fig. 6.

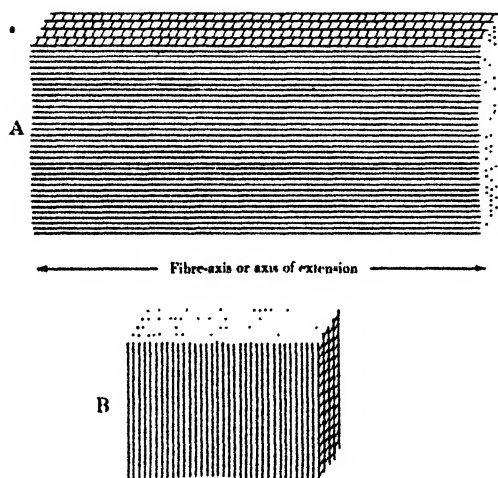

Fig. 7. Two ways of orienting crystallites (parallel bundles) of peptide chains by stretching denatured protein. *A*, long chains (keratin, denatured edestin etc.); *B*, short chains (denatured egg-white).

Films of denatured egg albumin were also made from urea solution (5% dried protein and 44% urea). The solution was spread on glass, allowed to evaporate, and the urea crystals washed out, after which several superposed strips were pressed between pieces of plate glass. Strips of the resulting film were stretched in 0.5% aqueous NaCl at 40°, but extensions of the order of 70% only were realised before rupture. The X-ray photograph of this urea film appeared to be of the type mentioned above as having been obtained with edestin fibres made from urea solution and excelsin films made from calcium chloride solution; that is to say, it showed not only the side-chain and backbone reflections, but also another reflection of spacing about 6 Å. Furthermore, orientation was shown by the side-chain reflection only, indicating that the length of the main-chains was more nearly equal to the thickness of the crystallites in the direction of the backbone spacing than was the case with the films of poached egg-white; in fact, one may think of the crystallites in the urea egg albumin films as more of the nature of square than oblong tablets.

It will be convenient to resume the discussion of the structure of the above-described denatured fibres and films after a short account of the results obtained with single excelsin crystals. One further point however may be noted here, *viz.* that they were all shown to be insoluble in water or 5% aqueous sodium chloride.

*Crystalline excelsin.*

The detailed X-ray investigation of crystalline excelsin will be reported later, but the unique results even now available have such an important bearing on the theme of the present paper that a brief preliminary account is offered at once, though only on the understanding that no finality is claimed at the moment.

Rapid dialysis of excelsin solutions gave microscopic hexagonal plates, whilst crystallisation from alcohol-water-sodium chloride gave rhombohedra. Very slow dialysis at 25° of a solution containing 2% protein and 10% NaCl gave however unusually large plates, up to some 2 mm. across, of a variety of shapes (mostly pentagonal) apparently derived from the hexagonal by inequalities of growth and truncation by rhombohedral and different prism faces. Owing to the demands of other work at the time these large excelsin crystals were unavoidably—but fortunately, as it happens—stored for some weeks in water.

For the first trial a crystal was lodged on the top of a short glass capillary tube the lower end of which dipped into a tiny trough of water, and the whole arrangement, which undoubtedly kept most of the crystal wet, was mounted on the X-ray spectrometer. The crystal was then photographed with the basal plane oscillating 5° on either side of the direction of the X-ray beam. The result was a composite photograph showing not only large crystal spacings like those given by crystalline pepsin and insulin [Bernal and Crowfoot, 1934; Crowfoot, 1935], but also an unmistakable fibre pattern. A similar composite photograph, not quite so sharp, was obtained also from a similarly oriented crystal dried in the air and mounted in the ordinary way. Furthermore it was demonstrated that it was unnecessary to oscillate the crystal in order to obtain the fibre diagram, as is usual in the X-ray examination of natural fibres. With the X-ray beam perpendicular to the basal plane another set of large crystal spacings was obtained and quite a different fibre diagram, very obviously multiple this time and symmetrical about a triad axis and three planes of symmetry. Finally intermediate fibre patterns were obtained with intermediate positions of the crystal.

The detailed analysis of these composite excelsin photographs will probably take some considerable time, but already it is clear that the fibre pattern corresponds fairly closely to the powder photographs of tobacco-seed globulin and squash-seed globulin (and probably edestin) described recently [Astbury and Lomax, 1935]. It is definitely not a fibre pattern corresponding to that of fully-denatured edestin (Fig. 5). At the moment it appears that the original crystal structure is symmetrical about a triad axis perpendicular to three dyad axes, and that it degenerates into six sets of fibrous crystallites lying approximately parallel with the basal plane, with the side-chain spacing (11.4 Å. wet) also roughly parallel and the backbone spacing (4.55 Å.) roughly perpendicular to this plane. Even after this metamorphosis followed by drying in the air the crystals retain their sharp outlines and remain perfectly transparent and isotropic along the triad axis. Drying the crystals in the air was found to reduce their water content from 39.2% to 11.8% of the crystal weight (or from 64.4% to 13.3% of the protein weight). Their solubility in 5% aqueous NaCl at 25° was found to be 14 mg. of protein per 100 ml., though undenatured excelsin forms thick opalescent solutions.

Preliminary attempts have been made to obtain corresponding results from edestin crystals, but hitherto the latter have yielded little more than the backbone spacing in random orientation. Edestin crystals are cubic however and the presence of four triad axes instead of only one might be expected to lead to more or less random degeneration.

## DISCUSSION.

Three main questions raised by the present communication invite a few concluding remarks: (1) that of successive stages of degeneration or denaturation; (2) that of the apparent striking difference in chain-length between denatured egg-albumin and edestin; (3) that of the structure of the unaltered seed globulins and the actual mechanism of their degeneration.

(1) The present experiments show directly that the seed globulins pass through at least one intermediate stage before final denaturation. This intermediate stage is fibrous but uncommonly well crystalline for a fibrous protein, in which respect it resembles feather keratin [Astbury, 1934, 1, 2]. It seems to correspond to the *proteans*, *edestan*, *excelsan* *etc.*, described by Osborne [1924, Chap. viii], who determined the amounts of such products generated during contact with water or dilute acids. In this connection it should be noted that the excelsin crystals examined by X-rays were also found to have almost lost their solubility in salt solution (see above); they would perhaps be more correctly described therefore, not as excelsin, but as excelsan.<sup>1</sup>

Other X-ray results quoted above also suggest the existence of successive stages of degeneration or denaturation: excelsin itself for instance, presumably denatured and at any rate quite insoluble and in the form of parallel chain-bundles, has not yet been brought to give a fibre pattern of the strict  $\beta$ -keratin type; and both edestin and egg albumin, though it is true that each gave such a photograph finally,<sup>2</sup> have been shown to give a slightly different fibre pattern, like that of excelsin, in fact, under certain conditions of denaturation. In view of these findings, if it should turn out that the  $\beta$ -keratin type of pattern is indeed a sound general criterion for the last stage of denaturation, then it may be found convenient to adopt the proposal put forward at the beginning of this paper, that the term "denatured" be reserved for this final state and the term "degenerate" for intermediate states.

It should perhaps be emphasised that though a coagulated, fully-denatured protein is probably always configurationally analogous to  $\beta$ -keratin in the sense that it consists of bundles of parallel peptide chains, the converse is by no means true. A protein may be built out of parallel polypeptide chains, *e.g.* myosin [Weber, 1933; Astbury and Dickinson, 1935], yet still retain its solubility and other characteristic properties. Such proteins may be said to be "configurationally disposed" towards denaturation: once the chains are given the chance of more intimate lateral contact, by drying for instance, the system denatures with extreme readiness. The properties of myosin illustrate this point well, and even gelatin becomes progressively more insoluble on long standing.

<sup>1</sup> One curious point must however be mentioned, *viz.* that the specimens of tobacco-seed globulin and squash-seed globulin whose X-ray powder photographs most closely correspond to the fibre diagram given by the degenerate excelsin crystals are still largely soluble in salt solution, whereas the edestin specimen (only a minute amount was available for test) is apparently not. But it would be profitless at this stage to discuss the significance of such an isolated observation: it is obviously necessary to study a much wider range of specimens before attempting any definite conclusions as to the interrelations between degeneration, solubility and X-ray diffraction pattern; and in any case it is clear enough from other results reported above and elsewhere that there are important variations among the seed globulins, whether degenerate or not.

<sup>2</sup> In spite of its unfamiliar lay-out the egg albumin photograph (Fig. 6) may be described for present purposes as of the  $\beta$ -keratin type, though exact correspondence cannot be considered to have been proved till better resolution has been attained through more perfect orientation of the crystallites.

(2) It was found that solutions of edestin in 20% aqueous calcium chloride gave only brittle, non-elastic fibres when squirted into water. The globulin under these conditions is not denatured, and as might be expected, is now incapable of producing true fibres in the molecular sense. Solutions in urea however, as already described, do give genuine fibres which are beautifully elastic when wet, for this solvent denatures the globulin. These urea solutions can be very viscous, and the development of such a property obviously corresponds to the increase in viscosity reported by Loughlin and Lewis [1932], for example, when egg albumin is denatured, the explanation of which is now clear. In the light of the present X-ray observations the denaturation of a "globular" protein such as egg albumin or edestin must almost certainly be accompanied by an increase in viscosity and, moreover, may open up the possibility of spinning true (probably elastic) fibres. As we have seen, this twofold prediction is fully confirmed in the case of the seed globulins, but it is only half justified in the case of egg albumin. Solutions of egg albumin in urea are comparatively thin and give when squirted into water only the poorest fibres which break almost at a touch. Films are more coherent and elastic but still do not show anything like the extensibility and elastic range of denatured edestin films.

This behaviour is just what one might infer from the X-ray photographs. Viscosity, extensibility and diffraction pattern all agree therefore in suggesting that the peptide chains in denatured egg albumin are relatively short, and clearly there is here a most promising line of attack on the structure of the unaltered globular proteins. It would hardly be justifiable at the moment to discuss exactly how, but it seems more than likely that the greater solubility of the albumins as compared with the globulins will ultimately be traced to the difference in chain-length revealed by X-ray examination of the denatured state.

(3) A reasonable inference from the experiments described above is that the unaltered structure of the seed globulins must be fairly closely related to the fibrous configuration of the proteans, otherwise one would hardly expect the degeneration of excelsin to cause so little disturbance of the external form and internal symmetry of the original crystal structure. Perhaps a factor contributing to this minimum of disturbance is the sixfold nature of the seed globulin molecules; for according to Svedberg and his collaborators they are made up of stable groups of six protein units of weight 34,500, which might conceivably be already joined by primary valencies. But whether this be so or not, a simple rearrangement of valency bonds consistent with existing experimental data to produce straight from folded chains may be illustrated diagrammatically thus:

Bernal and Crowfoot [1934] recently suggested a ring-chain polymerisation analogous to the formation of polyoxymethylene from trioxymethylene in order to explain the production of peptide chains when the globular protein pepsin degenerates [Astbury and Lomax, 1934, 1, 2], and Bernal [1934] has expressed the

opinion that long peptide chains do not pre-exist in the albumins and globulins at all; but experimental evidence at the moment is inconclusive, and some such transformation of a "gridiron" structure as that given above might very well harmonise the chain aspect of proteins with the polymerisation mechanism proposed by Bernal. The excelsin results reported here do certainly appear to support the polymerisation idea in a most striking fashion, yet it seems improbable that all degeneration of globular proteins so develops, and the difference in chain-length between denatured egg-albumin and denatured edestin may be due, in part at least, to the non-occurrence of polymerisation when the former is produced.

However that may be, it may now fairly be claimed that the link has been found between the long-chain proteins typical of natural fibres and the globular proteins investigated by Svedberg. Globular edestin has been transformed into elastic threads of what may now appropriately be called  $\beta$ -edestin, globular excelsin has been photographed in the actual process of polymeric degeneration into an intermediate fibrous form, and egg albumin itself, almost the prototype of globular proteins, has also been shown to be changed by denaturation into peptide chain-bundles similar to, but shorter than, those found in denatured edestin. The significance of these results in the study of fibre-building in the living organism may be very great indeed. Above all they strengthen the hypothesis that such fibre-building is no other than a kind of controlled and directed manifestation of the familiar "laboratory" degeneration of proteins, and that the X-ray photograph of feather keratin, for instance, contains not only the pattern of extended polypeptide chains, but also the dimensional impression left by the smaller units from which they were originally constructed [Astbury, 1934, 1, 2].

Needless to say, it is intended to examine shortly excelsin crystals which have not been allowed to stand long in water, but continued progress in the elucidation of the inner structure of the globular proteins must depend much on being able to catch intermediate forms such as the proteans. It cannot be over-emphasised that the keratin-like  $\beta$ -form appears to be in general only the last product of successive stages of degeneration.

#### SUMMARY.

1. The X-ray interpretation of protein denaturation suggests that it always involves the liberation or generation of peptide chains which aggregate on coagulation into parallel bundles like those found in the structure of  $\beta$ -keratin and similar fibres.
2. For the globular protein edestin this has been confirmed directly by the preparation of denatured elastic threads and films which give, on extension, an X-ray photograph analogous to that given by stretched animal hairs etc.
3. Denatured egg-white, when stretched, gives also an X-ray photograph of a similar type, though of an orientation which can be explained only if the peptide chains are much shorter than those found in  $\beta$ -keratin and denatured edestin.
4. Crystalline excelsin has been photographed in process of symmetrical degeneration *in situ* into an intermediate fibrous form provisionally identified with excelsan.
5. The results support the polymeric theory of the formation of fibrous proteins and provide a link between the structure of the natural fibres and that of the globular proteins.

We wish to express our great indebtedness to the Rockefeller Foundation for financing this research, and our sincere thanks to Prof. A. C. Chibnall for his practical interest in the work and his invaluable advice on chemical points.

# CCLXXX. NITROGEN METABOLISM OF CERTAIN INVERTEBRATES.

BY RICHARD TRUSZKOWSKI AND SOFIA CHAJKINÓWNA.

*From the Biochemical Laboratory, Faculty of Medicine,  
The University, Warsaw.*

*(Received August 29th, 1935.)*

NEEDHAM [1935] made the statement that "in the insects excretion of uric acid as the main end product of nitrogen catabolism is widespread, if not universal". Przyłęcki's paper [1926] on the nitrogen metabolism of invertebrates indicates that this statement is perhaps more comprehensive than the facts would warrant. For this, and other reasons, the problem in question was reinvestigated, not only for a number of insects but also for members of other phyla.

The present research, whilst concerned chiefly with purine catabolism, also includes data for other nitrogenous catabolites. In most cases, the presence or absence of uricase, xanthine oxidase and urease was established and in addition the uric acid content of the animals was determined wherever possible.

## GENERAL EXPERIMENTAL METHODS.

The animal material was ground up in a mortar with 10 times its weight of water (in the cases of Mollusca and earthworms clean sand was added). The suspension was strained through gauze to retain the larger fragments (chiefly the chitin integument in the case of insects and smooth muscle in that of other animals) and the filtrate was centrifuged (2000 r.p.m.: 5 min.). Portions of the centrifugates were examined for xanthine oxidase by adding an equal volume of 0.1 % suspension of xanthine in water and heating one portion at 100° for 5 min. Toluene was then added, and the mixtures were placed in a thermostat at 37°; portions of the solutions were examined after 24 and 48 hours for uric acid.

Urease was detected by adding 4 ml. of 0.5 % urea to 4 ml. of centrifugate and determining  $\text{NH}_3$  by aeration after 2 hours at room temperature. The controls consisted of similar systems in which the centrifugates had been heated at 100° before addition of urea, or in which water was taken in place of the centrifugates.

Uricase was detected in the residues obtained by centrifuging the suspensions or in suspensions of whole animals by suspending the precipitates in 10 ml. of 0.1 % uric acid solution (prepared by dissolving 1 g. of uric acid in 500 ml. of boiling saturated aqueous  $\text{Li}_2\text{CO}_3$ , cooling and diluting to 1000 ml.), heating part of the suspension at 100° for 5 min., cooling and determining the uric acid content of the heated and unheated systems after 24 and 48 hours at 37°.

Uric acid, when present in the aqueous extracts of the animals, was determined colorimetrically, by the original method of Folin and Denis, using a reagent not containing molybdic acid.<sup>1</sup> The reagent did not give any coloration with phenols, but gave positive reactions with sulphides and substances containing the SH group. The interfering effect of sulphides and thiol compounds is however only apparent and may lead to misleading results only when the fresh

<sup>1</sup> Merck's sodium tungstate is suitable, without purification, for preparation of the reagent.

extracts are studied; thus, a solution of  $\text{Na}_2\text{S}$  which gave a coloration corresponding with 1.2 mg. of uric acid per ml. immediately after preparation gave no coloration whatsoever after incubation at  $37^\circ$  for 18 hours. Analogous results were obtained with alloxan and with thiolacetic acid. In practice therefore the coloration given by the extracts after 24 hours at  $37^\circ$  may be assumed to be due chiefly, if not exclusively, to uric acid.

The presence of uric acid was also established in certain cases by positive murexide reactions given by the dry residues of deproteinised extracts.

Determinations of uric acid in the extracts were also performed as follows: the solutions were made feebly acid with acetic acid and boiled, the filtrates were made alkaline with  $\text{Na}_2\text{CO}_3$  (roughly to  $p_{\text{H}}$  9), and 0.2 g. of dry ox-kidney uricase (prepared by a method of Truszkowski and Gubermanówna [unpublished]) was added to a portion of the solution. The solutions, with and without uricase, were incubated at  $37^\circ$  for 24 hours, and uric acid was determined; in most cases the systems containing uricase gave no coloration, but where a positive reaction persisted the uric acid content was taken as being proportional to the differences in intensity of coloration of the two systems.

In view of the specificity of the action of uricase, it must be considered that the method described is one of the most trustworthy, both for the detection and for the determination of uric acid and has the further merits of simplicity and economy of time.

## RESULTS.

1. *Crayfish* (*Potamobius astacus*). Only the liver was examined; the results (Table I) are in accordance with the findings of Truszkowski and Goldmanówna [1933] that uricase is present. Other enzymes were not investigated in this case.

Table I.

Table 1.

Animal	mg. uric acid per ml.			Uric acid content in mg. per g. of animals	mg. of NH <sub>3</sub>

2. *Black-beetle* (*Blatta orientalis*). Uricase and urease were not present. In this, as in all the remaining cases, xanthine oxidase was not found. The aqueous extract contained uric acid, the content of which was roughly determined as follows: 8 individuals, weighing 2 g., were ground up with 25 ml. of water, and the uric acid content of the filtrate was determined in this manner: 5 ml. of filtrate gave a coloration corresponding with 0.19 mg. of uric acid per ml. after 24 hours at 37°, whilst after incubation for the same length of time with uricase no coloration was given, whence the content of uric acid per g. of insect was calculated to be 2.4 mg. The actual value is probably considerably higher, as it is doubtful whether all the uric acid was extracted under the above conditions.

An extract (in 10 ml. of boiling saturated aqueous  $\text{Li}_2\text{CO}_3$ ) of 5 mg. of faeces collected from five beetles fed for 4 weeks on potatoes and beetroots gave only a very faint reaction for uric acid (<0.015 mg. per ml.); assuming the faeces to have the same uric acid content as the entire insects, 0.012 mg. might be expected. A larger quantity of faeces, accumulated over a period of several months, gave a uric acid content of 2.1 mg. per g.

3. *Cockroach* (*Blattella germanica*). Uricase and xanthine oxidase were not found. The uric acid content of these insects is higher than that of black-beetles. Ten insects, weighing 0.6 g., were ground up with 15 ml. of water; the uric acid content of the deproteinised filtrate was 0.6 mg./ml. corresponding with 15 mg. of uric acid per g. of live wt. Owing to the difficulty of accumulating the faeces of this insect in sufficient quantity, the presence of uric acid in the excreta was established only qualitatively.

4. *May-beetle* (*Melolontha*). The specimens were collected in Polesie (East Poland) in June, and were sent by post to Warsaw, where they arrived in a moribund condition. They were examined only for uricase and uric acid; uricase was absent, and the aqueous extract contained an amount of uric acid corresponding with 6.85 mg. per g. of insect.

5. *Aphides*. The specimens were taken from nasturtium plants growing in window-boxes in Warsaw. Uricase, xanthine oxidase and uric acid were not found.

6. *House-fly* (*M. domestica*). Various species of *Musca* were taken, without any attempts at closer identification. The uricolytic activity of the residue after centrifuging the extract was quite considerable and traces of urease were present. Uric acid was not found in the extracts, indicating either that it is not a metabolite of these insects, or that, if formed, it is completely decomposed by uricase. Owing to the difficulty in obtaining centrifugates completely free from uricase, it was not attempted to detect xanthine oxidase in this and in the succeeding cases.

7. *Blow-fly* (*M. carnaria*). As in the preceding case, closer identification was not attempted. The uricolytic activity of these insects is even greater than is that of house-flies; it is probable that the activity of the preparation of uricase from this source surpasses that of any other studied up to the present. Uric acid was absent as in the case of house-flies.

8. *Honey-bee* (*Apis mellifica*). Worker-bees in good condition were taken. Uricase was not found, but the extracts gave only a very faint reaction for uric acid.

9. *Earthworm* (*Lumbricus*). Specimens from garden soil were examined by grinding with sand and water. Uricase, xanthine oxidase and uric acid were not found.

10. *Anodonta*. These were collected from semi-stagnant water near Warsaw. Uricase was present in the foot, but not in the mantle (the same results were obtained by Truszkowski and Goldmanówna [1933]), xanthine oxidase was

not found and urease is probably absent. Uric acid was not present in the extracts.

11. *Helix pomatia*. Uricase and xanthine oxidase were not found, urease and uric acid were present. These results are in agreement with those of Przyłeki [1922; 1926] and of Baldwin and Needham [1934].

12. *Limnaea stagnalis*. The specimens were taken from pools in the vicinity of Warsaw. Uricase and xanthine oxidase were not found.

#### DISCUSSION.

The findings for the somewhat heterogeneous group of invertebrates studied do not support the view that uric acid is invariably an end-product of the nitrogenous metabolism of insects; the notable exceptions were the house-fly and the blow-fly, which possess high degrees of uricolytic activity and which probably surpass any other known source of uricase in this respect. The same insects possess appreciable quantities of urease, which is absent from the other animals studied. The type of metabolism corresponding with these findings is one which would enable the flies to derive energy from the waste products of other animals, and this is in accordance with the mode of life of these insects and with their capacity of dealing with the most varied nutritive substances.

Amongst the Insecta uric acid was found in appreciable amount in the black-beetle, cockroach and May-beetle, the highest value (15 mg. per g.) being found for the cockroach. In view of the absence of xanthine oxidase and of uricase, the uricotelic type of metabolism is the most probable for these insects.

Certain of the animals examined possessed neither uricase nor uric acid (*Aphides*, earthworm, *Limnaea stagnalis*); it must be supposed that the nitrogenous metabolism of these animals is one in which uric acid is not an intermediate or final product. The position of the honey-bee is somewhat uncertain, since uricase is absent but only traces of uric acid are present; this animal requires closer investigation.

The type of nitrogenous metabolism corresponding with the enzymic equipment of *Anodonta* would be one in which uric acid is not a normal metabolite, although uricase is present. Truszkowski [1928] expressed the view, based on determinations of purine nitrogen before and after autolysis of the tissues of this animal, that the end-product of their purine metabolism is xanthine; the present findings support this opinion.

Finally, none of the animals examined gave evidence of the presence of xanthine oxidase, from which it might be concluded that uric acid in the invertebrates has a different origin from that of mammals.

#### SUMMARY.

1. Xanthine oxidase was not found in any of the phyla examined.
2. House- and blow-flies were found to be strongly, and crayfish and fresh-water mussels feebly, uricolytic; uricase was absent from the black-beetle, cockroach, May-beetle, honey-bee, *Aphis*, earthworm and Roman and pond snails.
3. A simple and trustworthy colorimetric procedure for the detection and determination of uric acid in presence of substances also reducing Folin's reagent has been described.
4. Uric acid was found in the extracts of the black-beetle, cockroach, May-beetle, honey-bee and Roman snail and in the excreta of the first two animals.
5. Urease was present in the house-fly and the Roman snail.

6. A uricotelic nitrogenous metabolism is probable, on the basis of the above findings, for the black-beetle, cockroach and May-beetle and for the Roman snail.

7. Przyłęcki's rule [1925] that uricotelic organisms do not possess uricase is confirmed.

The authors have pleasure in acknowledging their gratitude to Prof. St J. Przyłęcki for his help and advice during the execution of the above research.

# CCLXXXI. THE BEHAVIOUR OF *l*-ASCORBIC ACID AND CHEMICALLY RELATED COMPOUNDS IN THE ANIMAL BODY. THE INFLUENCE OF GENERALISED ETHER ANAESTHESIA ON THEIR URINARY EXCRETION.

By SYLVESTER SOLOMON ZILVA.<sup>1</sup>

*From the Division of Nutrition, Lister Institute, London.*

*(Received August 30th, 1935.)*

IN a recent communication [Zilva, 1935] evidence was produced showing that when compounds of the ascorbic acid series, *i.e.* *l*-ascorbic acid, *d*-arabo-ascorbic acid, *d*-galacto-ascorbic acid, *d*-gluco-ascorbic acid, *l*-gluco-ascorbic acid, were injected into guinea-pigs previously depleted of vitamin C, only the antiscorbutically active members were "fixed" by their tissues. In addition there was an indication that a quantitative relationship existed between the degree of activity and the amount "fixed", since the tissues of the animals injected with *l*-ascorbic acid showed a higher content than those of guinea-pigs treated with *d*-arabo-ascorbic acid (activity 1/20th of that of *l*-ascorbic acid). Furthermore, the amounts of the above compounds excreted by the kidney varied inversely with their antiscorbutic activity.

The present results not only confirm the above observation but reveal a new factor underlying the main phenomenon. In the first investigation the compounds were injected either by the intracardiac or intraperitoneal route without an anaesthetic or intravenously under a local anaesthetic (novocaine). No significant differences were observed in the urinary excretions of the respective compounds injected in either of these ways. The following results show, on the other hand, that when ether is employed as a general anaesthetic during the intravenous injection the amount excreted in the urine is increased.

In Table I the figures obtained by the use of the general anaesthetic are compared with those obtained in the experiments of the first communication when no anaesthetic or a local one was used. The assessment of the purity of the compounds and their concentration in the urine was made by titration with indophenol in each case. The difference in the urinary output was most marked with the "fully active" *l*-ascorbic acid and rather less marked with the "partially active" *d*-arabo-ascorbic acid—the output of the former being doubled when the intravenous injection was performed under the general anaesthetic. The effect of this anaesthesia was less evident when the "inactive" *d*-gluco-ascorbic acid or *d*-galacto-ascorbic acid was injected. The influence of the general anaesthesia thus becomes less with the diminished antiscorbutic activity of the compounds used.

It is of interest to note, nevertheless, that the use of the general anaesthetic did not prevent the "fixation" of the vitamin in the tissues. This is seen from Table II which shows that the quantitative distribution of *l*-ascorbic acid in the body after its injection into vitamin C-depleted guinea-pigs under these

conditions was even of a somewhat higher order than that observed when no anaesthetic or a local one was employed [*cf.* Zilva, 1935]. The higher excretion by the kidney under ether anaesthesia cannot, therefore, be due to deficient "fixation" in the body.

As previously mentioned the quantities of the various compounds voided in the urine were calculated from their indophenol titration figures. *L*-Ascorbic acid is excreted in the urine unchanged by human beings under normal conditions [Johnson and Zilva, 1934] and this is most probably also the case in animals with *L*-ascorbic acid and its related compounds when no general anaesthetic is employed during the injection. The possibility of an abnormal metabolism of these substances when ether is employed as an anaesthetic must, however, be borne in mind, although this appears at the moment to be improbable. An investigation which is now under way will, it is hoped, elucidate the significance of the influence of the general anaesthesia described above. The object of this note is to supplement the previous communication on the subject.

# CCLXXXII. THE PROPERTIES OF BLUE FLUORESCENT SUBSTANCES FORMED BY OXIDATION OF VITAMIN B<sub>1</sub> (QUINOCHROMES).

By HENRY WULFF KINNERSLEY, JOHN RICHARD O'BRIEN  
AND RUDOLPH ALBERT PETERS.

*From the Department of Biochemistry, Oxford.*

*(Received August 31st, 1935.)*

It has been stated previously [Peters, 1935] that a blue fluorescent substance arises by oxidation of the non-fluorescent vitamin B<sub>1</sub>. We have found that oxidation does not immediately destroy all properties of the vitamin, and we have accordingly explored in detail the changes in the formaldehyde azo-colour reaction [Kinnersley and Peters, 1934], in the state of the S and in the biological activity. New points have come to light. Windaus *et al.* [1932] had stated that permanganate oxidises the S in vitamin B<sub>1</sub> to —SO<sub>4</sub>. Our work shows that oxidation in the cold does not necessarily destroy the biological activity or remove S from the molecule; we have further evidence that other forms of vitamin B<sub>1</sub> exist, one of which may be blue fluorescent. This latter is yellow in acid solution unlike vitamin B<sub>1</sub>; the fluorescence disappears upon strong reduction and reappears upon reoxidation. We believe that these points are of immediate interest in relation to the problem of the grouping which is biologically active in this vitamin and of wider interest because they may shed some light upon the puzzle as to the function of the blue fluorescent substances in living tissues.

## HISTORICAL.

During early attempts to concentrate vitamin B<sub>1</sub> in yeast extracts, we noticed their marked blue fluorescence. Bence-Jones [1866] had found blue fluorescent substances in animal tissues, which he called "quinoidine" owing to a blue fluorescence similar to that of quinine. In 1925, Kinnersley *et al.* [1925] confirmed the presence of quinoidine and its resistance to permanganate. They considered that several different blue fluorescent biochemical substances existed but could not find a pure biochemical substance showing this property among a large number tested. They produced evidence however suggesting that the blue fluorescent substance in urine was urochrome.\* Vitamin B<sub>1</sub> proved not to be a "quinoidine" [Kinnersley and Peters, 1928]. Rosenheim [1927] observed a blue fluorescence in ergosterol (from yeast) which he thought to be due to oxidation products. More recently interest in these substances has been revived by the discovery of the flavins [Warburg and Christian, 1933; Kuhn *et al.*, 1933], though at first there was no clear appreciation of the difference from these latter compounds. Euler and Adler [1934] have reinvestigated the distribution of blue fluorescent substances particularly in the eye. Some of the degradation products of the flavins and substances allied to them fluoresce blue under some conditions [Karrer *et al.*, 1934 (lumichrome, formula 1); Kuhn and Bär, 1934; Stern and Holiday, 1934]. As a general term for such blue fluorescent substances mentioned above, we suggest the word "quinochrome"; this brings the term into line with lyochrome. For a chronological account see Table I. From

\* For references see paper by Kinnersley *et al.* [1925].

previous work upon the flavins, it might be thought that these were the major source of quinochromes in yeast. Since it has now been found that vitamin B<sub>1</sub> can give rise to blue fluorescent substances, quinochromes obviously can arise also from this vitamin. Recently Kuhn *et al.* [1935] have reported the isolation from the blue fluorescent substances in yeast of a sulphur-containing base of similar empirical composition to dehydrogenated vitamin B<sub>1</sub>. They call this thiochrome<sup>1</sup> and believe it to be a degradation product of vitamin B<sub>1</sub>. The inference that our oxidation products and thiochrome are intimately related is obvious; they are alike in several respects, but differ somewhat in solubility.

Synthetic work in collaboration with ourselves has been undertaken by Prof. Robinson (see Robinson and Tomlinson [1935] for the synthesis of the thiopyrimidazines III).

I. Lumichrome

II. Williams's formula for vitamin B<sub>1</sub>, written to show relation to I and III

III. Tetrahydrothiopyrimidine

<sup>1</sup> After completion of this paper, Barger *et al.* [1935] described the preparation of thiochrome from vitamin B<sub>1</sub> by ferricyanide.

*The properties of vitamin B<sub>1</sub>.*

In Table II the properties of the vitamin are summarised particularly with the idea of showing the changes dependent upon variable  $p_H$ . The zones of  $p_H$  are only approximate and intended to bring out the broad differences. It is clear that the outstanding changes in its properties occur about  $p_H$  7.0, which is striking in view of its biochemical activity; the properties to study from the standpoint of activity must be clearly those which change at this  $p_H$ . It will be noted that the effect of alkali upon the vitamin colour reaction [see Kinnersley and Peters, 1934] is irreversible, but upon the colour spectrum and titration curve it is reversible. But the spectrum from  $p_H$  1 to 4 shows another complication. When dissolved in acid alcohol, the vitamin shows a band at  $247 m\mu$  with a higher extinction coefficient than that of a specimen of vitamin which is acidified after being dissolved in 80% alcohol. This procedure would not inactivate the vitamin [Holiday, 1935]. In the case of the titration curve, differences occur with the hydrogen electrode as compared with the glass electrode. Both methods, however, indicate the presence of a pseudo-acid group in the vitamin. From the summarised evidence we can infer the independence of the band at  $247 m\mu$  and the activity, and of the latter and the pseudo-acid group.

References: (1) van Veen [1933]; (2) Kinnersley *et al.* [1935]; (3) Peters and Philpot [1933]; (4) Smakula [1935]; (5) Holiday [1935]; (6) Birch and Harris [1935]; (7) Moggridge and Ogston [1935]; (8) Kinnersley and Peters [1934]; Wintersteiner *et al.* [1935].

The  $p_K$  values of the two basic groups at  $p_K$  4.8 and 3.4 agree well with the  $p_H$  required to form the mono- and di-sulphate respectively [Kinnersley *et al.*, 1935]. Their interpretation upon the Williams formula is not obvious. Following observations of Levene and Simms [1926], who showed that pyrimidine amino-groups had  $p_K$  4.0-4.6, Moggridge and Ogston [1935] concluded that the group at  $p_K$  4.8 in the vitamin might be identified with the 6 —NH<sub>2</sub> group. They pointed out the difficulty that this would leave the quaternary N atom out of account in the titration, because the weaker basic group would have to correspond with one of the N atoms on the pyrimidine ring. This is possible; cyclic N in histidine has  $p_K$  6.18 [Birch and Harris, 1930]. It seems to be more likely now that the S decreases the effective basicity of the quaternary N atom. It is known that S influences the precipitation of bases by phosphotungstates in this direction [Peters, 1930]; the precipitation point of thioglyoxalines is more

acid than that of the glyoxalines by some 4-5  $p_H$  units. Further, Richardson [1933] determined the dissociation constants of *dl*-thiolhistidine, obtaining  $p_K$  1.84, 8.47 and 11.4 for  $-\text{COOH}$ ,  $-\text{NH}_2$  and  $-\text{SH}$  respectively. These are to be compared with histidine,  $p_K$  1.77, 6.18, 9.18 for  $-\text{COOH}$ , cyclic N and  $-\text{NH}_2$ . Here S appears to have abolished the  $p_K$  of the cyclic N. If the S in the vitamin is having such an influence, then  $p_K$  4.8 must be due to the N of the thiazole group and  $p_K$  3.4 to the 6  $-\text{NH}_2$ . Certainly the  $p_H$  at which the pseudo-acid group influences the titration would be consistent with this interpretation.

*The amino-group.* Williams and Gurin [1935] have stated recently that vitamin  $B_1$  interacts slowly with nitrous acid to produce nitrogen. The reaction must be a very slow one; using crystalline vitamin  $B_1$ , after a thorough nitrous acid treatment, the crystals were recovered in 75% yield and with no change in property (Exp. 5). Making allowance for the small scale of the work, the destruction could not have been more than 10%. This is entirely consistent with previous evidence upon impure vitamin as to stability to the action of nitrous acid.

*The thiazole group.* The recognition of a thiazole ring as a constituent of the vitamin  $B_1$  molecule by Williams and his colleagues and the definite identification by Tomlinson [1935] of synthetic 4-methylthiazolecarboxylic acid with the nitric acid oxidation product of Windaus *et al.* [1934] does not solve all problems in relation to the state of the S in the vitamin. The S is not present as  $-\text{SH}$  until after warming with alkali, to which the thiazole structure is usually stable. The vitamin must react with the ring intact and cannot function like glutathione by the  $-\text{S}-\text{S}-$  to  $2\text{SH}$  mechanism at a biochemical hydrogen ion concentration, owing to the relatively drastic treatment needed to free the S. Windaus *et al.* [1932] stated that warming with alkali splits off  $\text{H}_2\text{S}$  and also  $\text{NH}_3$ . We have devoted a few experiments to this point (Exp. 6), and have clear evidence that S will appear as  $\text{H}_2\text{S}$  after heating with alkali under conditions which leave the N intact. Evidently the state of the S is different from that in insulin [Freudenberg and Wegmann, 1935] in which  $\text{NH}_3$  and  $\text{H}_2\text{S}$  are stated to be formed simultaneously by heating with alkali. It is well known of course that insulin has no curative action upon vitamin  $B_1$  symptoms, but in case anyone should think that vitamin  $B_1$  might be the active group in insulin, it may be mentioned that an unpublished experiment by one of us (R. A. P.) showed that insulin after hydrolysis had no action as vitamin  $B_1$ .

*The formaldehyde azo-reaction.* (Vitamin  $B_1$  colour reaction.) This was described by Kinnersley and Peters [1934]. To a rather alkaline carbonate mixture are added diazotised sulphanilic acid, and after an interval the vitamin solution containing a drop of formaldehyde, added immediately before mixing. An immediate yellow colour appears which becomes pink after some 10 min. The maximum intensity is reached in an hour, and it will remain stable for many days.

It has not been mentioned so far that this reaction does not occur in the presence of reducing agents. It is not due to the presence of groups reacting as the S in thioglyoxalines, because the vitamin does not give the Hunter reaction [1930]. It is given to some extent by acetone. The vitamin gives a reaction of Hunter for thymine,<sup>1</sup> in which after treatment in sodium carbonate with the diazo-reagent, strong NaOH and hydroxylamine are added, to yield a reddish colour. On the whole, the vitamin reaction seems to resemble most those given by certain oxygen-containing pyrimidines [Johnson and Clapp, 1908].

<sup>1</sup> We are indebted to Prof. G. Hunter for allowing one of us to see part of a thesis, containing a description of this reaction. In his classification, the vitamin colour reaction would be regarded as of the keto-enol type [cf. Koessler and Hanke, 1922.]

The special properties of vitamin  $B_1$  which lend themselves to study are the catatorulin activity (brain enzyme test), the colour reaction, the liberation of  $H_2S$  on warming with alkali and the spectrum. This paper does not deal with the last.

*Vitamin  $B_1$  quinochrome.*

Before proceeding to detail, we shall draw attention to the broad facts by a recent experiment.

Exp. 1. A blue fluorescent solution was prepared from vitamin  $B_1$  as follows:

0.92 mg. vitamin  $B_1$ .HCl (prep. 73.3) was dissolved in 0.82 ml. 15% ethyl alcohol ( $p_H$  about 5.5). 0.06 ml.  $MnO_2$  suspension was added and the whole shaken at room temperature ( $23^\circ$ ) for 5 min.: 0.04 ml.  $N/20$  NaOH was then added and the whole again shaken for 5 min. A blue fluorescence visible in daylight rapidly appeared after the addition of the alkali,  $p_H$  about 7.5. After standing for a further 5 min., the whole was reacidified with 0.08 ml.  $N/20$  HCl to  $p_H$  6.2; it stood 10 days at room temperature. The colour reaction was then nil, but there was a delayed azo-reaction (see below) of 20% of the original.

This solution was tested upon an avitaminous brain and gave the result that 0.61% of the fluorescent products was equal in catatorulin activity to 0.52% of the untreated vitamin, i.e. there was not more than 17% diminution in activity. Such fractions may also be curative to birds.

Is the fluorescence due to conversion of a small part of the vitamin into inactive fluorescent products, or is a blue fluorescent substance itself biologically active? The fluorescence is most intense in alcoholic solutions in the region of  $p_H$  7.0, and solutions must be compared under these conditions. When acidified the solution becomes yellow, giving the whole a green appearance, which is stated to be also a property of thiochrome. We were early deceived by the extraordinary intensity of the fluorescence. Of our best fractions, such as that in Exp. 1, amounts of 0.5 mg. per ml. show marked fluorescence in daylight with a slight purple tint. As little as 0.5% per ml. shows good fluorescence in the ultraviolet (Hg lamp) light, of the same order of intensity as 3% per ml. of quinine sulphate (in  $N/80$   $H_2SO_4$ , 15% alcoholic solution). This is a conservative estimate; the colours are somewhat difficult to compare. The blue fluorescent products are certainly 6 times as fluorescent as quinine and more fluorescent than tetrahydro-alloxazine, for a specimen of which we are grateful to Prof. Robinson and Miss Tomlinson.

Hence by oxidation in this case a solution has been reached which is more fluorescent than some of the most fluorescent substances known, with a slight diminution in catatorulin activity almost within the experimental error. If the quinochrome were formed at the expense of 20% of the vitamin, it would have to be at least 30 times more fluorescent than quinine. As it is unlikely that any such substance exists, we conclude that the quinochromes themselves can be biologically active.

We have not obtained quinochromes by treatment with  $H_2O_2$ . In the first experiments they were produced by warming with traces of gold chloride (as we know now in very small amount). Maximum yields have been reached with permanganate and manganese oxides; the  $p_H$  is very important.

*Formation of quinochromes from vitamin  $B_1$  by manganese compounds.*

The main points reached in a series of experiments can be summarised under 9 headings. In this work we have found it convenient to carry out the oxidations in small test-tubes, containing 1-2 ml. of concentration 1-2 mg. vitamin per ml.

As the solutions often stood for several days, pure redistilled ethyl alcohol was added to a concentration of 15% to keep down the growth of micro-organisms. Control experiments showed that this made no difference to the results. In order not to interfere with subsequent attempts to isolate the products, no buffers were added, and the  $p_H$  was estimated colorimetrically upon a white tile and is therefore only approximate.

*Permanganate.* 1. At  $p_H$  5-5.5 oxidation with potassium permanganate ( $N/100$ ) takes place very slowly at room temperature; 2-4 hours are needed for completion, the permanganate being added drop by drop. During the oxidation 1 mol.  $O_2$  is taken up. Upon completion mere traces of fluorescence are present. The fluorescence may increase over several days, but is only a fraction of the total possible. Decoloration with permanganate will occur at as acid a reaction as  $p_H$  2 but it may take 24 hours for completion. It is therefore favoured by the ionised molecule. Barium permanganate does not give such good results.

At this stage there seems to be no interference with the properties of the vitamin, though the catatorulin activity may be a little diminished.

We do not understand what is happening in this step, possibly  $(6)NH_2 \rightarrow :NH$ . The permanganate is not oxidising traces of possible alcohol left in the crystals or traces of  $HCl$ ; this was excluded by controls. Assuming a definite oxidation the step must be reversible, because after removing the oxides of manganese, crystals of vitamin  $B_1$ . $HCl$  have been recovered with all the usual properties, M.P., colour reaction and activity. They can further be re-subjected to a fresh oxidation with permanganate.

2. After 1, if the solution is brought to  $p_H$  7-7.5, the fluorescence gradually increases during 10 days to a maximum. Heating the solution increases the rate of formation with a decrease in the total quinochrome yield. The pseudo-acid group is still present after 1, because the  $p_H$  has to be stabilised by addition of traces of alkali. During the course of this the azo-reaction tends to disappear and to be replaced by a delayed colour reaction, in which the solution after mixing with the diazo-reagent shows no colour for an hour or more. The catatorulin activity is present though variable.

3. With addition of more alkali to  $p_H$  8.0, less fluorescence is produced; a further amount of permanganate can be taken up at this stage, up to 2 mols. of  $O_2$  being recorded in one experiment. There appears to be destruction or oxidation beyond the fluorescent stage.

4. An oxidation started at  $p_H$  8.0 produces a poor yield. The changes detailed in 1-3 can be completed much more quickly by adding the brown oxides of manganese (thoroughly washed) formed in an oxidation of oxalic acid. Hence there are really two steps in 2 and 3, the last being due to the oxides formed in the first.

5. *Oxides of manganese.* Addition of the oxides of Mn at  $p_H$  5-5.5 gives practically no fluorescence even upon standing for 30 min.

6. After 5, if the  $p_H$  is taken to 6.8 (short of  $p_H$  7.0) there is an immediate fluorescence, visible to the naked eye. At first there is little change in colour reaction or catatorulin. After standing for a few days the colour reaction changes to the delayed type, and there is an improved yield of quinochrome. In a particular case the fluorescence increased as follows, 10 being considered to be maximum, 30 min. 0.5, 2 hours 1.0, 1 day 5.0. At this  $p_H$ , 6.5-7.0, more fluorescent substance has been formed than in any other way.

7. After 5, if the  $p_H$  is brought to 7.6 approximately, there is again immediate fluorescence, but the colour reaction is less stable and the total yield less, unless the  $p_H$  is brought back to 6.

Table III. *Progress of azo-reaction and blue fluorescence in oxidised vitamin solutions.*

Prep. $p_H$	Days after start

Numerator is blue fluorescence in terms of maximum 10  $\equiv$  at least 60 quinine sulphate.  
 Denominator gives azo-reaction Normal:: Delayed in terms of maximum 10.  
 For details of the preparations see Experimental, and Table V.

\* 30 $\gamma$  taken for the test. On 8th and 9th days 10 $\gamma$  gave negligible reaction.

8. When brought back to  $p_H$  4.0 there is an immediate change of the quinochrome solutions to a yellow colour with change in the tint of fluorescence.

9. Treatment with the oxides abolishes the pseudo-acid shift. There is negligible formation of  $-\text{SO}_4$  during these oxidations; the end result is a solution which gives no reaction for  $-\text{SH}$  on warming with alkali, or even on fusion with Na or K in amounts which for the vitamin would give a strong reaction. However, the S can be converted into sulphate and so identified by Carius oxidation with nitric acid in a sealed tube. That the vitamin S can reach such a state may excuse previous failures to find it, but it is clear that these properties indicate a substance of different chemical behaviour from the usual vitamin  $\text{B}_1$ .

*Relation of blue fluorescence and the azo-reaction.*

The question may now be asked as to what is the relation between the different variables. That between the blue fluorescence and azo-reaction is treated in Table III, between the former and the nitroprusside reaction on warming with alkali in Table IV, and the exploratory experiments upon the biological activity in Table V. Records of the normal and delayed colour reactions are given in Table III as well as the blue fluorescence in terms of a standard at intervals after treatment with  $\text{MnO}_2$ . The fluorescence once formed is stable under these conditions and even remains stable if the  $p_H$  is shifted to 10 in the dark. There is no relation between the azo-reaction delayed or otherwise and the amount of the fluorescence. For instance, we have 73.1, Fl 1 azo nil; 73.3, Fl 10, while azo-reaction falls from 3:4 to 0.5:2, and 74.4 Fl 5-7.5 while azo-test is 6:8 and 4:4. There is a tendency for the azo-reaction to fall off more quickly when the  $p_H$  is greater than 7 (*cf.* 74.2 against 74.4). There is a general correlation between the loss of the property of forming  $-\text{SH}$  on warming with alkali and the appearance of quinochrome (Table IV). The provisional conclusion is that azo-reactions and formation of quinochrome are independent reactions, but that the latter is closely related to disappearance of  $-\text{SH}$ .

Table IV.  $-\text{SH}$  reaction with hot alkali, and blue fluorescence.

74.2	2	5 -
74.4	2	10 -
73.4	Trace	10

*Biological activity.*

Information upon this is comprised in some 20 catatorulin tests upon the brain enzyme system [Passmore *et al.*, 1933; Kinnnersley *et al.*, 1935] and 2 sets of curative tests upon pigeons. The curative tests prove that there can be still much biological activity left in specimens of vitamin treated with permanganate or manganese oxides and containing much quinochrome. The value of 4 $\gamma$  per day dose must be accepted with the reserve imposed by the recent finding that crystalline vitamin does not give satisfactory tests [see Kinnnersley *et al.*, 1935]. The preparation might have seemed more active with a lower dose.

The catatorulin tests give more precise results and must be accepted as proof of action upon a specific enzyme system. The values have been obtained in media containing pyrophosphate, and as usual the relative maintenance of

respiration is the standard. They must be regarded as preliminary because in some cases it appeared that the shape of the curve relating dose to  $O_2$  uptake was changed in the oxidised samples.

Table V. *Biological tests.*

Fluorescence 10 maximum  $\equiv$  at least 60 quinine sulphate. ( ) indicates the number of birds upon which test is based. N, normal; D, delayed.

## A. Curative pigeon tests.

Preparation	Dates	Azo-reaction		Blue fluorescence	Catatorulin	Dose given	Day dose	No. of birds
		N	D					
57.7	iv. 35	0 :: 4		[5]*	9 -	20 $\gamma$	3.7 $\gamma$	(9)
59	iii. 35	2 :: 3.5		[5]*	6	20 $\gamma$	2.9 $\gamma$	(2)
74.2	vii. 35	0 :: 2.5		10	6	15 $\gamma$	2.7 $\gamma$	(9)

\* Blue fluorescence not accurately measured in the first two; the value in square brackets is judged from that reached in other experiments.

## B. Catatorulin tests.

Exp.	Preparation	Days after oxidation	Azo-reaction N D		Blue fluorescence	Catatorulin activity	Treatment
(a) Oxidised by manganese oxides.							
915	73.3	0	10	:: —	Trace	8	Shaken with MnO <sub>2</sub> at p <sub>H</sub> 5.0 only
914	73.2	0	6.7	:: —	[1]	10 +	p <sub>H</sub> 7.5 and brought back to p <sub>H</sub> 4.5 after 45 min.
926	73.3	10	Trace	:: 2	10	8.3	p <sub>H</sub> 7.5 for 5 min. and then back to acid p <sub>H</sub>
917	73.4	2	8	:: —	[3.5]	10	Kept at p <sub>H</sub> 6.9
921	73.4	4	5	:: —	[10]	7	
924	74.2	13	28	:: 8 +	3	4.2	Kept at p <sub>H</sub> 7.2
928	74.2	11	0	:: 2.5	10	6	-
923	74.3	3	0	:: 2.5	0.5	4.3	Oxidised in 90% alcohol at p <sub>H</sub> 7.0. (Exp. 2.)
928	74.4	10	2	:: 1.5	10	3.3	p <sub>H</sub> 6.5

For data on some of these tests, see Exp. 7.

## (b) Oxidised by permanganate.

820	57.7	22	7		[5]	8-10	Oxidised and kept at $p_H$ 7.5
821	57.7	27	4		[5]	8-9 +	
826	59	22	5	:: —	[5]	10 +	
829	59	24	—		[5]	5	—
830	59	25	2	:: 3.7	[5]	7	—
831	60	1	10	:: —	Trace	4	Oxidised and kept at $p_H$ 5.5 approx.

In the experiments marked 10 + there was a definite increase in the catatorulin effect above the maximum possible with addition of normal vitamin  $B_1$ . Square brackets means that the fluorescence was judged from other experiments.

Exps. 820, 926, 921, 928 show 5-10 fluorescence and high catatorulin activity.

Exps. 830, 918, 926, 928, 923 show poor azo-reaction and high catatorulin activity.

Exp. 928 shows high fluorescence and low catatorulin activity.

There seems to be a super-catatorulin effect amounting to some 10% in several of the specimens; this is marked in the table as 10+ (see also Exp. 8 for tests upon a worked oxidised fraction). It means that the catatorulin action of these specimens exceeds the maximum value possible with excess of vitamin  $B_1$ . Accepting  $\pm 1$  (10%) as the limits for the tests (in many cases they are more precise than this), the following is shown.

1. Specimens with high catatorulin activity, may show maximum fluorescence.
2. Complete loss of colour reaction is not necessarily attended with complete loss of activity.
3. An entirely oxidised specimen, from which all traces of vitamin B<sub>1</sub> proper have been removed, will still show catatorulin activity.
4. The conditions for forming quinochrome without loss of biological activity are not completely understood.

In interpreting these results, we must remember that much trouble has been taken in establishing in previous papers from this laboratory the fact that azo-reaction and catatorulin tests are satisfactory indicators of activity in crystalline vitamin B<sub>1</sub>. The general conclusion must be that other forms of the vitamin exist than the one which gives the normal azo-reaction, and that it is unlikely that there is not a quinochrome form of vitamin B<sub>1</sub> with different properties, at least as far as the S is concerned.

From the above work, it follows that there can be no direct relation between the group responsible for biological activity and that giving the azo-reaction, or between the structure especially responsible for the blue fluorescence and the activity; in view of the former conclusion this must include the state of the S.

In order to explain the experiments, there must be postulated as separate entities the quinochrome substance still giving the full azo-reaction, that giving the delayed reaction, and the fluorescent and non-fluorescent degradation products. In addition there is the elusive first product of permanganate oxidation. For a summary of the oxidation stages, see Table VI.

Table VI.

Oxidation stages	Azo-test	Catatorulin	Pigeon	—SH	—S fusion	Fluorescence	Colour in acid	Pseudo-acid
Vitamin B <sub>1</sub>	+	+	+	+	+	—	0	+
Intermediate product	+	+	+	+	—	—	0	+
Quinochrome A	±	+	+	Nil	Nil	+	Yellow	—
Quinochrome B ? thiochrome	?	—	—	—	—	+	Yellow	—
Non-fluorescent degradation products								

The formation of the intermediate product does not stop the pseudo-acid change, but is essential to production of the fluorescence (notes 6 and 7). The formation of A completely abolishes the pseudo-acid change, and acidification then gives the yellow colour at  $p_H$  values more acid than  $p_H$  6.0, in strong solution visible at 7.0.

*Properties.* After removal of manganese oxides and evaporation to dryness with alcohol to remove the last traces of salt, the substances present in the blue fluorescent solutions form an oil and will not crystallise, nor will the addition of light petroleum to the alcoholic solution bring out crystals as with the pure vitamin. Mixtures of other solvents have so far not succeeded. The substances are soluble in ethyl and methyl alcohol and water, but only in traces in lipid solvents.<sup>1</sup> Solubility in chloroform is very low, and this seems to be a marked difference from thiochrome. No insoluble picrate or picrolonate could be made,

<sup>1</sup> Rangier [1935] states that urochrome, containing 2% S, is soluble in H<sub>2</sub>O and dilute alcohol but not in organic solvents.

nor silver salt at acid  $p_H$  values. The only promising precipitant was mercuric chloride with sodium acetate, both in excess. Fractional precipitation from any unchanged vitamin can be carried out with this reagent, because unchanged vitamin requires less of the reagents for precipitation. It has not proved possible to purify the mercuric chloride compound upon the small scale. Analyses upon 3 different samples, gave  $HgCl_2$  70% ( $Hg$  60% approx.),  $N$  5–6% and  $C$  9–13%. The  $C/N$  ratios were nearest to  $C_{12}N_4$  ( $C_{10}N_4$  in 2 of the samples).  $C_{9-12}N_3$  was excluded by the analyses.

Treatment of the mercuric chloride complex with  $H_2S$  precipitates the quinochrome for the most part as an adsorption complex with the sulphide, from which it can be freed with hot water. In its ease of adsorption, it resembles rather closely the flavins, and it is very readily adsorbed upon vitamin  $B_1$  hydrochloride crystals. The loss of biological activity at the gold stage in the preparation of crystals of vitamin  $B_1$  is associated with the adsorption of blue fluorescent substances upon the gold sulphides from which they can be extracted by pyridine-methyl alcohol-water, following the technique of Kuhn *et al.* for flavins. In this connection it may be mentioned that Schopfer [1934] states that certain apparently pure specimens of flavin still contained traces of vitamin  $B_1$ , sufficient to affect the growth of micro-organisms. It seems most likely that this was the quinochrome form.

The oxidation-reduction properties of the quinochrome are rather negative as for the flavins. It is not reduced by  $H_2S$  or ascorbic acid. No change in fluorescence was seen upon incubation anaerobically in a Thunberg tube with an active succinoxidase solution. But sodium hydrosulphite readily reduces quinochrome to a leuco-compound, which again becomes fluorescent upon re-oxidation. The implied stability to sulphite is interesting in view of the ease with which vitamin  $B_1$  itself has been shown by Williams *et al.* [1935] to be degraded by sulphite. In neutral or acid solution the fluorescence is stable to strong light (Exp. 4). After reading the statement of Kuhn *et al.* [1935] as to the instability of thiochrome upon illumination in alkaline solutions, we have found that this is also a property of our solutions.

#### DISCUSSION.

The empirical formula and blue fluorescence of the vitamin oxidation products together with their general adsorption behaviour led to the hypothesis [Peters, 1935] that vitamin  $B_1$  might be a thiopyrimidine (hexahydrothiolumichrome). In support of this, it was found that the thiopyrimidines made by Robinson and Tomlinson could be readily converted into quinochromes by permanganate oxidation about  $p_H$  7.0, with removal of  $S$  as  $SO_4$ . This view is not now tenable for at least 3 reasons; vitamin  $B_1$  appears to be a pyrimidinethiazole compound [Williams, 1935]: blue fluorescence arises without removal of  $S$  as  $SO_4$  as we have shown here: and thiochrome [Kuhn *et al.* 1935], a  $S$ -containing substance, has a blue fluorescence. But the idea that the blue fluorescent substance may be produced by ring formation between the  $-NH_2$  at 6 and the  $-CH_3$  [Robinson and Tomlinson, 1935] is still tenable. From the present work it appears that formation of quinochrome is coincident with loss of the pseudo-acid shift and loss of the  $-SH$  reaction upon warming. Change in the valency of the  $N$  atom from quaternary to tertiary might well account for this and might accompany the closure of another ring. Evidently the critical  $p_H$  for the formation of active quinochrome with permanganate is about 7.0, which coincides with the  $p_H$  at which the basic groups become practically un-ionised and with the start of the pseudo-acid shift. The immediate appearance of some

10% at least of the fluorescence at room temperature is curious. The substances formed certainly resemble the thiopyrimidazines in colour, but not in ease of crystallisation or in solubility in aqueous solutions. Formation of a third ring by closure in the 6 position should be accompanied by a slight change in basicity which might be revealed by titration. Upon the views here expressed there should be a change in the alkaline spectrum after oxidation to quinochrome A. Some preliminary results have already been obtained in this direction by our colleague Dr Holiday, whose work will be reported later; it will be noted that the spectrum of thiochrome shows no alkaline change.

The question arises as to how far the Williams formula accounts for the groups responsible for the colour reaction and the biological activity. The brain enzyme work published from this laboratory implies that the vitamin acts as an acceptor or donator of  $-H$  or  $-OH$  in some oxidation-reduction system. We can readily picture the changes upon oxidation and closure of the ring. Closure of the ring and change in the S must be simultaneous. Reasons have been given against any belief that we are dealing with a sulphhydryl-disulphide system; and the independence of the S behaviour and the biological activity do not suggest a direct relation with this part of the molecule. Our provisional conclusion is that both the biological activity and the colour reaction are connected with the  $-NH_2$  group at 6, which would therefore be capable of existing in two states of oxidation  $-NH_2$  and  $-NH^+$ . Upon such a view the nitrogen atom in the closed azine ring might be still able to function as H acceptor and donator. It is indeed quite conceivable that the blue fluorescent oxidised form may represent the actual biologically active state. This would explain the excess catatorulin activity noticed in several experiments.

The connection of the colour reaction with the  $-NH_2$  at 6 would explain the strict relation between colour reaction and activity in the normal vitamin and the changes in the colour reaction which take place during gradual closure of the ring. If the first stage of oxidation is from  $-NH_2$  to  $-NH$ , we can picture the intermediate stage as follows:

We have often been driven in our work to a belief that more than one form of vitamin exists [Kinnersley and Peters, 1928]. It is satisfactory to have more direct evidence for this. Some of the properties of the more impure vitamin concentrates, which are known to differ from those of the crystals, may be explained by the presence of these modifications of the vitamin. The matter is now under investigation.

#### EXPERIMENTAL.

*Note.* Comparison of the intensities of the fluorescence of different samples has been made with the aid of quinine standards.

*Exp. 2. Oxidation of vitamin B<sub>1</sub> in concentrated alcoholic solution by manganese dioxide.* Previous to the observation that vitamin B<sub>1</sub> on oxidation formed quinochrome, it had been noticed that alcoholic solutions of vitamin B<sub>1</sub> on standing in the cold or at room temperature for variable periods up to several months contained a blue fluorescent substance. (Care must be taken to use extracted corks since a blue fluorescent substance is freed from cork by alcohol.) A quinochrome is formed in small amounts and is rather insoluble in water.

<sup>1</sup> This would be consistent with the change of the  $p_K$  3.4 group when titrating with the hydrogen electrode.

At 0° it is produced more rapidly the nearer the  $p_H$  is to 7, whilst very little of it is formed at  $p_H$  2. The substance is made more quickly by the addition of manganese dioxide in 85% alcoholic solution and an adjustment of the  $p_H$  to approximately 7. In prep. 74·2 for instance the fluorescence produced was not by any means maximum but was almost instantaneously formed; after oxidation, about half the catatorulin activity was left with no colour reaction. (See Table V, B (a).)

Exp. 3. *Comparison of the rates of formation of fluorescence at  $p_H$  5·5 and  $p_H$  7·5.* To 1·14 mg. vitamin HCl in 1 ml. 15% alcohol was added an excess of  $MnO_2$ . The mixture was shaken for 5 min. adjusted to  $p_H$  7 and again shaken for 15 min. after which the  $p_H$  was brought back to 5·5.

A similar solution of 1·19 mg. vitamin HCl was treated in the same way. The  $p_H$  was, however, maintained at 7. Comparison of the fluorescence of these two solutions showed that there was ultimately no difference in the intensity, but in the acidic solution the fluorescence tended to develop more slowly.

Preparation	Time				Units of fluores- cence
	2 hr.	3 days	4 days	6 days	
$p_H$ 5·5	Yellow	5	5	10j	
$p_H$ 7·0	Blue	5	10	10j	

10 regarded as maximum.

Exp. 4. *Effect of sunlight upon quinochrome.* (a) Comparison was made between two 15% alcoholic solutions of quinochrome each equivalent to 0·250 mg. original vitamin  $B_1$ ; in one case the  $p_H$  was adjusted to 7 and in the other to 9. After standing for three days, no difference was observed in their fluorescence. Exposure of the solution at  $p_H$  9 to sunlight for 1·25 hr. caused a 95% diminution in the intensity of fluorescence. No change was observed in the solution at  $p_H$  7.

(b) 0·25 mg. vitamin HCl in 0·25 ml.  $H_2O$  ( $p_H$  approximately 5·5) was oxidised by the addition of 0·25 ml.  $N/100 KMnO_4$  drop by drop. On exposure to sunlight for 1 hr., no diminution in fluorescence was observed.

Exp. 5. *The action of nitrous acid on vitamin  $B_1$ .* 12·01 mg. of vitamin HCl were treated with 8·2 mg. barium nitrite in 0·45 ml.  $H_2O$  and 0·05 ml. HCl and allowed to stand for 3 hr. when a further 8 mg. of barium nitrite were added. The solution was thoroughly acid and the evolution of gas complete. After heating on the water-bath the solution was treated with 0·05 ml. baryta, saturated at room temperature and the whole worked into absolute alcohol at  $p_H$  3. By colour reaction, 4000 doses of vitamin were present corresponding to 8·0 mg. After removing the inactive precipitate of  $BaCl_2$  which gave no colour reaction, 8·8 mg. of vitamin  $B_1$  crystals were isolated giving normal colour reaction and catatorulin activity.

The recovery was therefore at least 75% not allowing for certain unworkable residues, so that not more than 10% was destroyed.

Exp. 6. *Liberation of sulphur from vitamin  $B_1$  by treatment with alkali.* 10·83 mg. of vitamin HCl were dissolved in 1·5 ml.  $H_2O$  and added to 150 mg.  $Ba(OH)_2$ . The mixture was heated on a water-bath for a total period of 1·25 hr. Volatile gases were expelled by blowing nitrogen through the mixture and collected in 7·55 ml.  $N/100 HCl$  which at the end of the experiment required exactly 7·55 ml.  $N/100 NaOH$  for neutralisation. We concluded that no ammonia had been liberated from the vitamin under these conditions. The mixture was acidified with 2 ml.  $2N H_2SO_4$  and again heated. The liberated  $H_2S$  was expelled by a stream of nitrogen into a 12·5% solution of lead acetate

containing 1 or 2 drops of acetic acid and weighed as lead sulphide. The total amount of sulphur converted into  $H_2S$  was approximately 40% of that present in the original vitamin.

The residual solution after the above treatment, brought to  $p_H$  3, showed a strong blue fluorescence. Like quinochrome, this blue fluorescent substance is precipitated by mercuric chloride and sodium acetate. In view of the fact that only part of the sulphur was removed by alkali treatment it seems probable that the fluorescence is due to quinochrome itself since the sulphur in this compound is not very labile to alkali.

In Table VII the different amounts of  $H_2S$  formed by alkali in several experiments are given. In no experiment have we been able to detect the liberation of ammonia. In some experiments attempts were made to collect volatile mercaptans by alcoholic mercuric chloride solutions. No evidence was obtained of sulphur produced in this form from the vitamin by action of alkalis.

Table VII.

Exp.	Wt. of vitamin mg.	Reagent	Amount of $NH_3$ liberated	Amount of S liberated (%)
1	11.63	N NaOH	Nil	58.8
2	5.42	"	"	15.4
3	3.4	"	"	47.5
4	2.4	"	—	74.5
5	10.83	10% baryta	Nil	40.0

Sulphur was determined as lead sulphide except in the case of Exp. 4 where it was weighed as barium sulphate.

Exp. 7. *Catatorulin tests*. The catatorulin tests (see Table V) were made for the most part on the cerebrum of the avitaminous pigeon in head retraction. (The cerebrum gives better duplicate values.) Several had to be rejected owing to insufficient depletion of the cerebrum in vitamin. Pyrophosphate was present in the medium and the technique was essentially that described in a previous paper by Kinnersley, O'Brien and Peters [1935, Appendix]. The data for  $O_2$  uptakes for three typical experiments for a period of respiration of 1–2 hr. are given in Table VIII. It must be remembered that 1.0 $\gamma$  normal vitamin gives practically maximum increase in respiration.

Table VIII.

$O_2$  uptake for 1–2 hr. period expressed as  $\mu l./g./hr.$

	Normal vitamin		Unknown		
	Weight of vitamin ( $\gamma$ )	$O_2$ uptake	Preparation	Weight ( $\gamma$ )	$O_2$ uptake
914	2.28	$1142 \pm 3.5\%$	73.2	0.76	$1048 \pm 4\%$
	0.38	$848 \pm 1\%$		0.253	$791 \pm 2.5\%$
921	2.5	$1505 \pm 1.2\%$	73.4	5.0	$1360 \pm 1.7\%*$
	0.67	$1287 \pm 1.0\%$		1.0	$1335 \pm 0.5\%$
926	3.0	$1550 \pm 2\%$	73.3	5.0	$1522 \pm 1\%$
	0.3	$1246 \pm 0.5\%$		0.61	$1407 \pm 3\%$

NOTE. The mean is recorded with  $\pm$  deviation of the duplicates from the mean.

\* Not used in computing the results because the respiration decreased at an abnormal rate.

Exp. 8. *The preparation of blue fluorescent material free from vitamin  $B_1$* . 20.63 mg. vitamin  $B_1$  HCl were oxidised with  $MnO_2$  at  $p_H$  7.5 for 5 days. Fluorescence appeared rapidly and at no time was there evidence of the formation of sulphate during the oxidation. The colour reaction gradually changed to

the delayed type and on the third day was 0:4. The whole was concentrated *in vacuo* at  $p_H$  7 and worked into 1 ml. absolute alcohol at  $p_H$  7; 3 ml. light petroleum were added which removed traces of insoluble material. The filtrate was further concentrated to 0.3 ml. and 0.7 ml. light petroleum was added. A few very fine needles separated after standing 2 days in the cold room. At this stage any unchanged vitamin would have precipitated. The filtrate from the needles was very yellow and fluorescent; to it were added 2 similar fractions from 21.5 mg. and 4.93 mg. amounts of vitamin.

An 18 $\gamma$  sample of the total filtrates containing 35 mg. of oxidation products gave a colour reaction: normal, nil, delayed 8, and fluorescence not more than 2. The catatorulin activity of these fluorescent products is shown in Exp. 918 where comparison is made between the effect of normal vitamin  $B_1$  and that of the fluorescent substances on the respiration of avitaminous pigeon brain. It is seen that the oxidation products gave an increased catatorulin effect, greater than the maximum of the normal vitamin.

Exp. 918.

Normal vitamin		Fluorescent preparation	
Weight ( $\gamma$ )	O <sub>2</sub> uptake $\mu\text{l./g./hr.}$	Weight ( $\gamma$ )	O <sub>2</sub> uptake $\mu\text{l./g./hr.}$
1	1506 $\pm$ 3.7%	10	1617 $\pm$ 3%
0.33	1090 $\pm$ 1%	1	1515 $\pm$ 1.6%

Note the increased activity over 1 $\gamma$  normal vitamin.

Exp. 919 shows the increase in O<sub>2</sub> uptake with increasing concentrations of the fraction.

Weight of fraction ( $\gamma$ )	O <sub>2</sub> uptake $\mu\text{l./g./hr.}$
Nil	1000 $\pm$ 8.1%
0.5	1142 $\pm$ 4.3%
1.0	1390 $\pm$ 1.2%
5.0	1637 $\pm$ 3.0%

From these experiments, there is no doubt that a fluorescent fraction from which all normal vitamin was removed is still biologically active.

#### SUMMARY.

1. Blue fluorescent oxidation products of pure vitamin  $B_1$  are produced at room temperature very slowly by the action of permanganate and manganese oxides at  $p_H$  values more acid than  $p_H$  6.0, more rapidly about  $p_H$  7.0. The substances formed are yellow in acid solution. Sulphur is not split off as sulphate but the state of combination of S changes. The vitamin  $B_1$  colour reaction (formaldehyde-azo-reaction) diminishes during oxidation, but not as in the case of alkali-labile S in proportion to the development of the fluorescence.

2. The fluorescent oxidation products show biological activity even in absence of the normal colour reaction; hence other forms of vitamin  $B_1$  exist than the one at present isolated.

3. The sulphur is split off as  $H_2S$  from vitamin  $B_1$  by a treatment with hot alkali which leaves the nitrogen intact.

4. Pure vitamin  $B_1$  reacts very slowly if at all with nitrous acid.

5. These changes are discussed in relation to the chemical constitution and biological activity.

We are indebted to the Medical Research Council for grants in aid of the research and for personal grants to two of us, also to R. W. Wakelin for skilful assistance.

*Note added September 29th, 1935.* Further work shows that large amounts of  $\text{CHCl}_3$  extract the blue fluorescent substance from aqueous solution and that the fluorescence of extracts in some cases exceeds the previous {maximum estimate, i.e. >6 times quinine.

# CCLXXXIII. THE MINERAL CONSTITUENTS OF BONE.

## I. METHODS OF ANALYSIS.

BY CLARICE MARGARET BURNS AND NELLIE HENDERSON.

*From the Department of Physiology and Bio-Chemistry, University of Durham College of Medicine.*

*(Received August 26th, 1935.)*

A KNOWLEDGE of the composition of the mineral constituents of bone is important for two reasons. First, the most popular view of the mechanism of ossification supposes that in bone formation a salt is precipitated from its saturated solution. The desirability of knowing exactly what salt is thus deposited has been considered by Shear and Kramer [1928, 1] and Roseberry *et al.* [1931]. Secondly, work on calcium metabolism frequently suggests that calcium is being laid down in, or removed from, bone [e.g. Greenwald, 1926; Greenwald and Gross, 1926], but it is impossible to detect these bone changes in the presence of the large amount of calcium stored there. If, however, bone salt were first deposited in some specific form which slowly changed to the salt of adult bone, or if some labile form of calcium were removed first, such changes might be detected.

Examination of the mineral constituents of bones of many species by physical methods [Taylor and Sheard, 1929; Roseberry *et al.*, 1931], or by chemical methods [Shear and Kramer, 1928, 1, 2; Morgulis, 1931], has established the fact that they consist largely of calcium, phosphate and carbonate in such proportions that the calcium may be assumed to be mainly carbonate and tertiary phosphate, and that they have the crystalline structure of the apatite series. By different chemical methods, Shear and Kramer [1928, 1] and Morgulis [1931] concluded that small quantities of  $\text{Ca}(\text{OH})_2$  are present in addition to the carbonate and phosphate. These workers assumed that all the carbonate was bound to calcium, and they calculated the ratio to the phosphate for the calcium not thus bound, *i.e.* the residual Ca/P. They found this ratio to average 1.99 (Shear and Kramer) and 2.04 (Morgulis), whilst for tertiary phosphate the theoretical figure would be 1.94.

In the examination of the ash from large numbers of young rats, Burns [1929] found a ratio for the total Ca/P ranging from 1.99 to 2.10, which approximated rather to that of the residual Ca/P than to the total Ca/P as found by the aforementioned workers. Hammett [1925] gave proportions of calcium and phosphate in the bone ash from young rats which showed a total Ca/P ratio of 1.89 to 2.04. It seemed therefore possible that the bones of young animals either contained little or no carbonate, or that there was present a form of phosphorus, which appeared as phosphate in the ash, but was not estimated as such by the methods of Shear and Kramer or of Morgulis. An attempt was therefore made to locate this phosphorus in the bone and to determine the influence of age on the composition of the bone salt.

Before analysis, the bones were dried at 100–110° and extracted with alcohol for 8 hours and ether for 16 hours, the epiphyses being previously torn off and treated separately. The same sample was used for carbon dioxide, calcium and phosphorus estimations; the solution for the last two was prepared during the estimation of the first, which was done by one of the following methods.

*Estimation of carbon dioxide.* 1. *Manometric method.* This method will estimate 0.13–0.63 ml. of  $\text{CO}_2$  corresponding to 0.015–0.13 g. of bone according to its degree of calcification. A Barcroft blood-gas manometer was used; 2 ml. of boiled distilled water were placed in each bottle and the weighed sample of bone in one. 0.45 ml. of 80% trichloroacetic acid was placed in each stopper, and the estimation was carried out exactly as for the determination of the  $\text{O}_2$  content of blood.

The Barcroft bottle was previously calibrated using a standard solution of sodium or guanidine carbonate, so that the constant included an approximate correction for  $\text{CO}_2$  remaining in solution. 1 ml. of 0.17% sodium carbonate or of 0.36% guanidine carbonate is a convenient quantity. Seven calibrations of 4 estimations each gave a maximum variation of less than 3% in each group.

The following analyses were carried out on a sample of ground bone to check the accuracy of the method:

$\text{CO}_2\%$  2.53, 2.51, 2.51, 2.62; Ca % 22.15, 21.95, 22.30, 22.75; % Ca as carbonate 10.40, 10.40, 10.20, 10.45. Maximum variation 2.5%.

2. *Titration method.* When larger amounts of bone were available for analysis the method used was a modification of that described by Van Slyke [1918]. The modifications consisted of (a) the use of 80% trichloroacetic acid to liberate the carbon dioxide, instead of the hydrochloric acid used by Van Slyke. Trichloroacetic acid is non-volatile and does not dissolve out protein when dissolving the salts of bone. (b) After the removal of the washed tube containing the bone solution from the flask containing the mixture of baryta and barium carbonate, the latter was not filtered off, but the baryta was determined directly by simple titration with 0.1 N potassium hydrogen phthalate with phenolphthalein as indicator. The acid potassium phthalate was without effect on the barium carbonate. This direct titration diminished the possibility of contamination with atmospheric carbon dioxide.

To avoid the formation of a thick protein precipitate which prevented the further action of acid on the bone, 2 ml. of boiled distilled water were added to the bone powder, which was mixed in the tube to form a smooth paste. Two or three drops of octyl alcohol were added to prevent foaming. Pure sodium and guanidine carbonates were used to test the method. Under a pressure lower than about 60 mm., the tap grease was not satisfactory and the vacuum was not preserved long enough to enable the reaction to go to completion in the bone. A pressure of 60–70 mm. was therefore used. The results of twelve estimations of carbonate in standard sodium carbonate solution gave an average error of  $-1.5\%$  and a range of error of  $-0.5$  to  $-3.0\%$ . On a similar batch on dry guanidine carbonate, the error ranged from  $-3.0\%$  to  $+2.0\%$  with an average of  $-1\%$ . Figures with an error of  $-5\%$  to  $-8\%$  were secured when a pressure of 110 mm. was used. To minimise the picking up of atmospheric  $\text{CO}_2$  by the baryta while it was being run into the conical flask, the baryta burette was fitted with a long tip which ran down to the bottom of the flask.

Compared with the manometric method the titration method showed the following percentage variations in a series of 10 duplicate analyses:  $-0.8$ ,  $-5$ ,  $-1.5$ ,  $-4.8$ ,  $+0.8$ ,  $+2.4$ ,  $+1.7$ ,  $+2.2$ ,  $+3.75$ ,  $+12.4$ . (This last high value did not agree with the Ca estimation on the same sample.)

*Estimation of calcium.* The extract of bone was made up to 2 to 10% of trichloroacetic acid according as the amount of bone used ranged from 0.01 to 0.1 g., and the volume chosen was such that 2–3 ml. of filtrate contained 0.6 to 0.8 mg. of Ca. Calcium was estimated as described by Burns [1933], and in this concentration the range of error was  $\pm 1\%$ .

*Estimation of phosphate.* Two methods were used. In the first a solution containing 2–5 mg. of phosphorus was brought to the boil and to each 100 ml. of the solution were added 60 ml. of an ammonium molybdate solution prepared according to the method of Cole [1926]. The solution was boiled for a few minutes and then allowed to stand on a hot bath till the precipitate had settled and the solution was clear and colourless. The filtered precipitate, washed free from acid with boiling water, was dissolved in 0.5 *N* NaOH. The ammonia was not boiled off, and the NaOH was titrated with 0.5 *N* HCl. With phenolphthalein as indicator it was found that 1 ml. of 0.5 *N* NaOH was equivalent to 0.675 mg. P. This method gave an accuracy of  $\pm 1\%$ .

The second method used was the colorimetric one of Fiske and Subbarow [1925]. The acidity of the trichloroacetic acid solutions was not found to interfere in this estimation, and in only one case did opalescence occur on the addition of ammonium molybdate. This method was used for the estimation of 0.04 to 2 mg. of P. The forms of phosphate estimated by these methods included the inorganic phosphate and any labile organic phosphate. Total phosphate in the trichloroacetic acid extract was estimated by the method described by Baldwin and Needham [1933]. For the colorimetric method, an accuracy of  $\pm 1\%$  was found in 80% of a large series of estimations on standard phosphates. The remaining 20% had an error not exceeding  $\pm 2\%$ .

The possible presence of phosphorus which was not extractable by cold trichloroacetic acid, but which would give phosphate on ashing, was tested by drying and ashing the washed residue from six samples after the trichloroacetic acid extraction had taken place. Dry ashing was done in the presence of sodium carbonate to prevent loss of phosphate. The subsequent estimation of phosphorus was done by the modification of their method suggested by Fiske and Subbarow [1925] for use in the presence of silica, since some silica was always picked up from the crucible. The six samples tested varied in weight from 0.2 to 0.5 g. and contained from 12 to 50 mg. of phosphorus. They included all the bone tissues, dense and cancellous bone, calcified and uncalcified cartilage and marrow. In only one of the six samples was as much as 0.6% of the original phosphorus left. This seemed to preclude the possibility of the presence in bone of a form of phosphorus not extractable by acid.

*Sampling.* A whole bone is often too large for analysis and half a bone may be unrepresentative, e.g. the upper half of a femur contained 14.4% and the lower half 10.4% of Ca. A whole bone, ground up in a coffee-mill, gave a powder which was not homogeneous. Moreover, if the whole bone is used for analysis differences in the individual tissues are overlooked; and the only information gained is the proportion of the whole structure which is calcified. Therefore, in order to follow the actual chemical changes which occur as bone is laid down, the following tissues have been examined separately; cartilage, calcified cartilage, cancellous bone, dense bone surrounding it, bone from the middle of the shaft and marrow. It is essential to use the whole of the cancellous bone, since it is not homogeneous in structure and composition, and different parts vary in degree of ossification by as much as 50%. When the quantity is inconveniently large, it is possible to make a representative mixture by grinding the tissue in a mortar. Cancellous bone may vary in quantity and composition under different conditions, so that it is necessary to know how far the specimens, removed by hacking them out with a penknife, are representative in either respect. Corresponding bones from the same animal were compared. Of samples from 14 pairs of small bones (diaphysis < 6 cm.) 5 differed in weight by 0–10%, 5 by 10–20% and 4 by 20–30%. A difference in weight of less than 30% could not therefore

be considered certainly significant. Two kid's femora, 12 cm. long, from which the epiphyses were not removed, were cut down the middle and the knee cancellous scraped out. Its weight in the two bones differed by 17%. In the same 14 samples, the CO<sub>2</sub> values of 9 pairs differed by 5%, of 4 by 5-10% and of 1 by 10.5%. A difference of over 10% in the carbon dioxide would therefore probably be significant.

For purposes of direct comparison with the above analytical methods, those used by Shear and Kramer [1928, 1] and by Morgulis [1931] were also tried.

A sample of powder from an adult bone shaft was analysed as above, while a second sample was extracted with hydrochloric acid and examined as by Shear and Kramer, except that the ammonium molybdate precipitate was centrifuged off instead of being removed by filtration. The calcium figures for the two samples were 24.38 and 24.42% whilst the phosphorus figures were 11.53 and 11.48% respectively. In the centrifuged solution, a faint precipitate appeared during the development of the blue colour. Therefore in the next sample, a fairly well calcified epiphysis, the ammonium molybdate precipitate was filtered off through ash-free filter-paper. In this sample, the total P estimated by Baldwin and Needham's method on the hydrochloric acid extract was 4.68% whilst the inorganic P as estimated by Shear and Kramer's method was only 4.36%. Large numbers of analyses have shown that in such bone the inorganic P determined by our method does not differ from the total P by more than 3%. In this sample therefore the % P as given by Shear and Kramer's method was low.

Two samples of fetal epiphyses of approximately the same age were examined by the two methods respectively. By the trichloroacetic method the first sample was found to contain Ca 0.51%: inorganic P 0.36%: total P 0.52%. (Cartilage has been found to contain a certain amount of non-inorganic phosphorus.) The other sample extracted with hot hydrochloric acid contained Ca 0.64%: total P 0.80% and inorganic P, 0.19, 0.22 and 0.28% according to the dilution of the solution in which the ammonium molybdate precipitation was carried out. Clearly the protein precipitate had carried down varying quantities of phosphate. In a further sample with total phosphate 1.45%, Kramer's method gave only 0.45 and 0.95% P according to dilution. The cancellous bone from a femur of a rabbit suffering from bone deformities was analysed by our method and gave Ca/P 2.18: residual Ca/P 1.78. The cancellous bone from the other femur was examined by Shear and Kramer's method. The total P was 3.14% and the total Ca/P was 2.20, residual Ca/P being 1.80, but by Shear and Kramer's method the P was only 2.33%, the Ca/P was 2.96 and the residual Ca, P was 2.43. A further 0.33% of P was found by washing filter-papers from four estimations free from soluble phosphate, igniting the filter papers and estimating the phosphorus in the ash. A considerable amount of the protein precipitate was washed through the filter-paper, and some phosphorus may have been lost in ignition, as sodium carbonate was not used, but the protein precipitate had obviously carried down appreciable amounts of phosphate [*cf.* Fiske and Subbarow, 1925; Goldblatt, 1935]. The method which involves filtering off the ammonium molybdate precipitate is therefore satisfactory for highly calcified bone in which little protein passes into solution but is increasingly unsatisfactory as the ratio of protein to phosphate in the solution increases, since more and more phosphate is carried down with the protein precipitate and the Ca/P ratio becomes correspondingly too high.

The method used by Morgulis consisted of removing the organic matter of the bone by heating it with 3% KOH in glycerol. The bone ash was left as a white salt which was washed with water and alcohol to remove the alkaline reagent.

Analyses for calcium, carbonate and phosphate were then made on the dry ash. This method was applied to a salt supplied as "pure calcium phosphate precipitated by ammonia" and to samples of different bones. In order that the results obtained by the two methods might be compared, it was necessary that they should be applied to ground and mixed samples. Neither powdered calcium phosphate nor the ash left after leaching out bone powder with the alkaline glycerol could be picked out of the reagent as described by Morgulis for pieces of bone. So the glycerol was decanted off into a beaker, and to it were added the water and alcohol washings from the salt. The glycerol and wash-waters were filtered through ash-free filter-paper, on which the washed salt was collected, as it was desired to determine the total calcium, phosphate and carbonate in the salt and not only the ratio. (If the alkaline glycerol was decanted directly on to the filter-paper, filtration took many days.)

The glycerol filtrate and washings were made just acid to phenolphthalein with hydrochloric acid, dried and ignited gently to a black ash in a silica dish. On this ash total phosphate and calcium were estimated, allowance being made for the probable presence of silica. Blank estimations on the reagent similarly heated in the silica dish gave only minute traces of calcium or phosphate (< 0.1 mg.). Before this method was applied to the "precipitated calcium phosphate" the latter was examined directly to determine the salt present. Considerable discussion has taken place previously, reviewed by Shear and Kramer [1928, 2], as to whether the salt precipitated by alkali from a solution containing calcium and phosphate is a specific compound, the tertiary salt, in equilibrium with the solution, whether it is a mixture of lime and secondary phosphate, with the latter in equilibrium with the solution, whether the secondary phosphate first formed subsequently reacts with the solution round it to give the tertiary salt, or whether in fact the tertiary salt is an actual chemical entity. Roseberry *et al.* [1931] have produced X-ray evidence that the tertiary salt can exist as a member of the apatite series but it is not clear from their work whether the samples they examined were prepared by simple precipitation. Four samples of the precipitated salt were examined by the above method in simple acid solution. They contained respectively Ca 33.5, P 18.6; Ca 34.4, P 18.8; Ca 34.8, P 18.9; Ca 34.2, P 18.8%; mean Ca/P 1.82. All the samples contained 0.2% CO<sub>2</sub> and traces of magnesium and chloride. They were free from ammonia and only lost 0.5 to 1% of moisture when heated at 100° for 4 hours, but lost 6–8% of their weight when heated in the blast furnace, total calcium and phosphate being unchanged. The heated salt contained 72.9% of its phosphate as orthophosphate and 27.1% as pyrophosphate. This suggested that 27.1% of the phosphate in the original salt was present as secondary phosphate but did not prove the chemical composition of the original mixture. Equal weights of secondary phosphate and lime, of di-acid phosphate and lime and of secondary phosphate and calcium carbonate were mixed intimately and samples heated gently and strongly, the products being examined for total and orthophosphate. In every mixture, strong heating produced salts containing more than 60% of the phosphate in the ortho-form, whilst gentle heat produced only 30–40% in that form. The di-acid salt gave some extremely insoluble metaphosphate and a mixture of pyro- and ortho-salts. These results could only be explained on the assumption that the pyro- or meta-salts first formed reacted on further heating with lime to give tertiary calcium phosphate, and that lime from calcium carbonate could be used for this purpose.

This is in agreement with the X-ray evidence of Roseberry *et al.* [1931] that this salt is a real chemical entity, but it does not prove that this salt is precipitated by alkali from solutions containing calcium and phosphate. An attempt to study the question as to whether tricalcium phosphate exists as such in the precipitate produced by alkali from a solution containing calcium and phosphate, and therefore possibly in bone at some stage of ossification, was made by studying the effect of gentle heat on such precipitates and on mixtures of lime and secondary phosphate. For this purpose the following were used: (1) secondary calcium phosphate; (2) a commercial precipitated calcium phosphate; (3) a mixture of equal weights of lime and secondary phosphate; (4) an air-dried freshly prepared calcium phosphate (Ca/P 1.88) precipitated from a solution just alkaline to phenol red; (5) a freshly prepared secondary calcium phosphate (Ca/P 1.44) made by precipitating calcium phosphate from a solution acid to methyl red and drying between filter-papers; (6) the secondary calcium phosphate from (5) dried in the air overnight on a glass plate; (7) a mixture of the secondary phosphate (5) with lime (Ca/P 5.3); (8) this mixture dried overnight on a glass plate. 0.2 g. of each of these substances was heated over a low burner regulated so that secondary phosphate was converted into pyrophosphate in 1 min. When 0.2 g. of the mixtures was heated on this burner for varying times, varying proportions of ortho- and pyro-salts were found.

From the results of these experiments the following facts may be deduced:

(a) The brief heating over the low flame sufficed to convert 99% of the dry secondary phosphate ( $\text{CaHPO}_4$ ) into pyrophosphate. Heating the air-dried secondary calcium phosphate converted 97% of the phosphate into pyrophosphate. This air-dried compound contained 39% water. (Here, as in all the water contents of these mixtures, the water was measured by the loss of weight on ignition to constant weight, and includes adherent moisture, water of crystallisation and the water lost from the molecule in converting secondary phosphate into pyrophosphate.) The Ca/P ratio was 1.44. This would be compatible with the presence of about 95% of the crystalline  $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$  and 5%  $\text{Ca}(\text{OH})_2$ , or of a mixture of 79.2% of  $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$  and 20.8%  $\text{Ca}_3(\text{PO}_4)_2$  with about 23% of the phosphate in the condition in which it would not be converted into pyrophosphate by heat. The precipitate from the phosphate solution made just acid to methyl red was therefore mainly the secondary salt mixed with small quantities of lime.

(b) In a mixture of equal weights of lime and secondary phosphate free from water of crystallisation (water content of mixture 10%), 12% of the phosphate was found as orthophosphate after 1 minute's heating, and 23.6% after 30 min. Since 99% of this phosphate heated alone was converted into pyrophosphate in 1 min., the orthophosphate found after heating the mixture 1 min. would not probably be unchanged secondary phosphate. However, the relatively rapid production of tertiary orthophosphate in the first minute and the slow subsequent production suggest two reactions. In the first stage while water is present, the process is practically one of heating a strong solution of lime and secondary phosphate, when presumably the reaction

occurs. Later, when all the phosphate has been changed into tertiary orthophosphate or into pyrophosphate, the slow reaction (1) (p. 2389) produces further orthophosphate.

(c) After being heated 1 min., calcium phosphate precipitated from an alkaline solution showed in one case 60.9 and in the other 79.3% of the total

phosphate as orthophosphate. Further heating for 30 min. only increased the proportion to 66.4 and 87.4 % respectively although ignition in the blast furnace brought the figures up to 82.5 and 94.6 %. The figures of 60.9 and 79.3 % may be compared with the 12.0 % of orthophosphate produced by heating a known mixture of lime and secondary phosphate for one minute. The precipitated calcium phosphate contained 7 and 15 % of water respectively, so that whilst some of the 60.9 and 79.3 % of the orthophosphate might be produced by heating the wet salt by the rapid reaction (2), it does not seem probable that this could account for the production of 60 % of tertiary phosphate in a mixture of water content 7 %, whilst only producing 12 % of orthophosphate in a mixture of water content 10 %. It seems therefore improbable that the precipitated salt consists merely of a mixture of lime and secondary phosphate, but seems much more probable that from 50 to 70 % of the phosphate found as orthophosphate after 1 minute's heating was in the form of tricalcium phosphate before the heating began. This is also supported by the water content of the mixtures. Lime,  $\text{Ca}(\text{OH})_2$ , contains 23 % of water even when free from adherent moisture, whilst crystalline secondary phosphate gives up on heating 26.1 % of water. It is difficult to see how any mixture of these, dried at a temperature not exceeding 15°, could give a mixture of water content 15 %.

It was not possible by this method to determine whether the tertiary phosphate was formed in contact with the solution or in the process of drying, since heating secondary phosphate with excess of wet lime caused such rapid formation of the tertiary salt. The mixture of lime and wet secondary phosphate, thoroughly ground together and air-dried, showed however a water content of only 17.5 %, from which it seemed probable that these salts in the presence of moisture had reacted to form some tricalcium phosphate. It was therefore fairly certain from these studies that the precipitated calcium phosphate to be examined by Morgulis's method was a mixture of tricalcium phosphate, secondary calcium phosphate and lime.

Samples of this precipitated calcium phosphate were treated with the alkaline glycerol, and the salt and extract were analysed as already described. Table I shows the results. In Exp. 3, part of the salt was not used for analysis, but was again treated with the glycerol reagent. Ignited salts were also sub-

mitted to the treatment. Further samples were treated with hot or cold aqueous alkali, and salt and solution were analysed. A sample of salt containing 96% secondary calcium phosphate and 4% di-acid calcium phosphate was also heated with 0.5 *N* aqueous NaOH.

It may be seen that after the salt had been strongly heated, treatment with either aqueous alkali or alkaline glycerol extracted little phosphorus and left the CO<sub>2</sub> content unchanged, and the ratio Ca/P for the final salt was very close to that for the initial salt. Where however the unheated salt was used, varying quantities of phosphate were removed in the extract, and the ratio Ca/P for the final salt always exceeded 1.94, that for tertiary phosphate. (Small quantities of the salt were occasionally washed through the filter-papers; when this did not happen the calcium of the alkaline extract was negligible. To avoid the tedious re-filtering of these solutions, this calcium was assumed to be present in the form of the salt on the filter, and the amount of phosphate combined in this form was subtracted from the total phosphate in the extract to determine the amount present in the soluble form.)

If it be assumed that in the presence of hot alkali the salts of the mixture react according to the equations (2) (p. 2390) and

then it would be expected that the resultant salt would be tricalcium phosphate, while one-third of the phosphate of that portion of the secondary salt which could not combine with lime would be found in the extract. A mixture of 84% tertiary calcium phosphate and 16% secondary calcium phosphate would have a Ca/P ratio of 1.82, and the phosphate of the secondary salt would be 17.95% of the total. It might therefore be expected that 5.95% of the total phosphorus would appear in the extract. Actually the phosphate in the extract always exceeded this and the Ca/P of the final salt indicated the presence in it of lime. This lime might be produced by the hydrolysis of either the tertiary or secondary salt, but its presence seems to be independent of the presence of lime in the original salt, since it was found when secondary calcium phosphate, free from lime, was treated with hot alkali. It would seem also more probable that it is the secondary salt which reacts in this way with the alkali, since the mixture of tertiary phosphate and pyrophosphate (Exps. 5 and 8) produced by ignition, and the mixture of tertiary phosphate and lime produced by treatment with alkaline glycerol (Exp. 6), reacted negligibly with the further alkaline treatment.

These experiments indicate very clearly that the composition of the salt produced by this treatment may differ very markedly from that of the original salt, although the method may be applied to phosphates known to be the tertiary phosphate or pyrophosphate. It would seem to be generally inapplicable to mixtures of unknown composition which might contain secondary or similar phosphates. Moreover, in these experiments some carbon dioxide was picked up by the salt.

Various samples of bone were examined directly and after leaching with alkaline glycerol. Table II shows the results, the figures marked *E* being secured by direct analysis, those marked *M* being the figures for analysis of the salt produced by the leaching out process. The carbonate is expressed as the percentage of the total calcium with which it could combine. In ten out of the fourteen bone samples used, the carbonate content of the salt as prepared by leaching out was from 15 to 25% higher than was indicated by the direct determination. Bones 11 to 14 were not ground up before analysis and could be lifted out of the solution and washed whole as described by Morgulis, only the traces

\* Salt picked out of solution and washed whole.

falling into the solution being washed on to the filter-paper. Exact duplicates of the samples could not be secured, but similar parts of bones from the same animal were examined directly and the carbon dioxide contents agreed as closely as for two estimations made on such material by the direct method. No duplicate for bone 11 was available, but its carbon dioxide content was not high for the age of the old cat from which it was taken. These results seemed to indicate that the extra carbon dioxide was picked up by the salt during the exposure to air necessitated by the very slow process of collecting the salt on the filter-paper. If the alkaline glycerol had reacted with the bone phosphate as with the mixture of phosphates to give some free lime, this lime exposed when moist to a slow filtration would pick up carbon dioxide. The true residual Ca/P ratio for the leached out salt is therefore shown in Table II in the Ca/P *M*, corrected for CO<sub>2</sub>. This residual Ca/P is deduced by using the CO<sub>2</sub> content of the salt as found by direct analysis and indicates more accurately the amount of lime produced by the alkaline treatment. If this corrected residual Ca/P is compared with the residual Ca/P found by direct analysis, it is seen to be in every case higher than the latter, although in bones 2 and 3 the difference is not outside the experimental error. When the residual Ca/P of the salt is corrected for the phosphate lost in the extract as well as for the CO<sub>2</sub> picked up, the resulting figures are found to lie within the experimental error of the figures found by direct examination and are not all ranged on one side of these figures; of the eight samples completely examined by both methods, five are slightly above and three slightly below the figures for direct analysis. Samples 1-4 and 12 were from the bones of two old cats and samples 5-8 from a young adult cat. Samples 9, 10, 11, 13 and 14 were from the bones of young rapidly-growing kittens. The figures for the dense bones of the old animals, samples 1, 2, 3 and 12, would indicate empirically that the leaching out method leaves a salt which can safely be used as a sample of the bone salt, but the figures for the cancellous bone of an old animal (sample 4), and all the bones of the younger animals, indicated that enough phosphate may be lost in the extract appreciably to affect the Ca/P ratio. Examination of further six samples of bone treated with aqueous or glycerol alkali, showed the removal of 2 to 10% (average 7%) of the phosphate in the alkaline extract. Morgulis tested the leaching out method on a salt of Ca/P ratio 1.92 and on a bone for which his figures indicate a residual Ca/P ratio of 1.93 by direct analysis and 1.96 by analysis of the leached out salt. For these salts, the method would give results closely similar to those by direct analysis, but samples 4 to 11, 13 and 14 indicate that bone salt may not always have this highly specific composition, and that the method is not therefore generally applicable, the residual Ca/P thus found being frequently appreciably too high.

The actual value of the residual Ca/P ratio in indicating the probable composition of bone salts may be questioned. The ratio is derived from three separate estimations—for calcium, phosphate and carbon dioxide, the range of error of which is such that a certain proportion of the figures for the Ca/P ratio must have an error of  $\pm 4\%$ . Thus a figure which ought to be 1.88 might be 1.96 or 1.80, but a residual Ca/P ratio of 1.88 would indicate the presence of about 10% of the calcium as secondary phosphate, whilst a ratio of 1.80 would mean that more than 20% of the calcium was in this form. Individual figures have therefore little value in indicating the form of combination of the calcium and phosphate. In a total of 18 samples done in duplicate, only 1 pair differed by as much as 2.5%. The eight samples shown in Table II have values for residual Ca/P by both methods which agree within  $\pm 2\%$ , when the necessary corrections for  $\text{CO}_2$  picked up and phosphate lost in the extract are made. The average of a large number of estimations will therefore give some information as to the composition of bone salt. There is, according to Kramer and Howland [1926], Hammett [1925] and Morgulis [1931], and from certain figures secured in the course of this work, an amount of magnesium in bone salt equivalent to about 1–3% of the calcium. If this magnesium is ignored in the calculation as here and in the papers of Shear and Kramer [1928, 1, 2] and Morgulis [1931], and if this magnesium is entirely combined with phosphate, a residual Ca/P of 1.88 to 1.92 would be compatible with the presence of all the calcium as the tertiary phosphate. On the other hand, if all the magnesium is present as carbonate, a residual Ca/P as low as 1.94 would not preclude the possible presence of small quantities of lime. The mean residual Ca/P ratio of 270 samples of bone from cats, dogs, rabbits, goats and sheep of varying ages was 1.85. This figure was also the mode. Table III shows how these figures were distributed through the total range of 1.68 to 1.97.

Table III.

Residual Ca/P	<1.76	1.76–1.80	1.80–1.84	1.84–1.88	1.88–1.92	1.92–1.96	1.96–1.97
% of samples	4.1	11.8	21.2	32.3	22.3	7.3	0.8

The range of 1.88 to 1.92 for the residual Ca/P, which in the presence of the magnesium would indicate that all the calcium phosphate was tertiary, was found in 22.2% of the cases. This range was exceeded in 8.1% of the samples, but 69.2% of the figures fell below it. This seems to indicate the probable existence in some samples of bone of small quantities of a phosphate other than tertiary calcium phosphate in the form of apatite, but, in view of the difficulties already discussed in the accurate determination of the residual Ca/P, it would seem that the existence of such a phosphate could only be regarded as proved if this phosphate were actually separated.

An attempt to study the question by igniting 14 samples of bone and examining the ash for pyrophosphate led to inconclusive results. In only two samples did the total phosphate exceed the orthophosphate by more than 3%, and these figures, 4.5 and 4.7%, were of doubtful significance. Since, however, precipitated calcium phosphate containing at least 20% secondary phosphate, when mixed with  $\text{CaCO}_3$  in the proportions of bone and heated as strongly as is necessary to ignite bone, only showed 0.3 to 4% pyrophosphate, the failure to find appreciable amounts of pyrophosphate in the ash resulting from the ignited bone must be regarded as inconclusive evidence as to the presence of secondary phosphate in the original bone salt. Attempts are being made to discover the degree of heating which will convert secondary phosphate into pyrophosphate in the presence of organic material, whilst causing the minimum production of tertiary phosphate

from the carbonate and the pyrophosphate. It is not impossible that some of the phosphate contained in bone is combined with alkali metals. Three kitten bones contained 0.18 to 0.22 % of potassium on the wet bone, equivalent to about 0.6 % of the salt. No analyses for sodium were made. Compounds of phosphate with organic substances are also possible, although if present they must be labile to heat or acid.

The variation in the composition of bone salt with age, species and diet is being investigated in greater detail.

#### SUMMARY.

1. Chemical evidence is adduced to support the view that the phosphate produced when calcium phosphate is precipitated from an alkaline solution and allowed to reach equilibrium with the solution actually contains tricalcium phosphate as well as lime and secondary phosphate.

2. Analysis of bone phosphate by a method which involves filtering off the precipitate produced by ammonium molybdate gives results which are too low. The resulting Ca/P ratio is therefore too high.

3. The salt produced by heating bone with alkaline glycerol is not accurately representative of the original bone salt. In all cases some phosphate is lost in the extract, though this amount may in some cases be extremely small.

4. Analysis of salt mixtures shows that the leaching out method is applicable to tertiary calcium phosphate or calcium pyrophosphate but not to secondary salts or mixtures containing these.

5. Methods are described for the analysis of the calcium and phosphate of bone with an average accuracy of  $\pm 1.5\%$ , and of the carbonate with an accuracy of  $\pm 3\%$ .

6. In 270 analyses of bone, 70 % of the figures for calcium, carbonate and phosphate were such as to indicate the probable presence in bone of a phosphate not tertiary calcium or magnesium phosphate.

The expenses incurred in this work were defrayed by a grant to Prof. Burns from the Medical Research Council for which we express our thanks.

# CCLXXXIV. THE EFFECTS OF OXIDATION-REDUCTION POTENTIAL INDICATOR DYES ON THE METABOLISM OF TUMOUR AND NORMAL TISSUES.

By KENNETH ALLAN CALDWELL ELLIOTT AND ZELMA BAKER.

*From the Cancer Research Laboratories, Graduate School of Medicine,  
University of Pennsylvania, Philadelphia, Pa.*

*(Received July 16th, 1935.)*

IN most of the studies made in recent years on the effects of dyes on the respiration and glycolysis of tissues, very low concentrations of dyes have been used. Using a relatively high concentration of 2:6-dichlorophenolindophenol,  $1.3 \times 10^{-3} M$ , Elliott [1934] found a peculiar difference between the behaviours of tumour and kidney tissues. The respiration of kidney tissue was always found to be almost completely inhibited by the dye; the respiration of tumour tissue in the absence of glucose was also completely inhibited, but, when glucose was present, tumour tissue continued to respire. It was of interest, therefore, to see whether this difference of behaviour in the presence and absence of glucose was a unique property of tumour tissue, and whether the behaviour with 2:6-dichlorophenolindophenol was a property shared by other reversible oxidation-reduction systems. Both these questions are answered in the affirmative, and various other points of interest are brought out in the following paper.

## EXPERIMENTAL.

The metabolism of thin slices of various tissues was studied in the presence and absence of dyes in the apparatus of Dixon and Keilin [1933], following the details of technique described by Elliott and Schroeder [1934]. The bicarbonate-containing medium of Krebs [1932] was used, and when glucose was added, this was made up to a concentration of 0.24 %.

### *2:6-Dichlorophenolindophenol.*

A stock  $1.3 \times 10^{-3} M$  solution of the dye was made up in glucose-free Krebs medium and standardised by titration against ascorbic acid by the method of Birch *et al.* [1933]. For experiments with glucose present, the necessary amount of a strong glucose solution was added to a portion of the dye solution shortly before use. Stock solutions containing the dye and glucose slowly lose bicarbonate; it is probable that the dye catalyses an oxidative breakdown of glucose with the formation of acid products.

In a concentration of  $1.3 \times 10^{-3} M$ , 2:6-dichlorophenolindophenol produced 80–100 % inhibition of respiration, whether glucose was present or not, with all the following tissues: rabbit and rat kidney cortex, rabbit and rat brain cortex, rat testis, rat retina and 4-day chick embryo. With rat liver, the inhibition varied between 30 and 89 %, the mean being 56 %, and in every case the R.Q. of the residual respiration was lowered, the mean effect being a drop in R.Q. from 0.95 to 0.60 (averages of 20 experiments). The presence or absence

of glucose caused no difference in the effects with liver, the average values for 10 experiments under each condition being the same. Tumour tissue (Philadelphia No. 1 sarcoma [Waldschmidt-Leitz, McDonald *et al.*, 1933] and Walker No. 256 carcinoma) alone showed a difference in the effect of the dye depending on the presence of glucose. In the absence of glucose, the respiration was always inhibited about 90% whilst with glucose present there was only a small, variable inhibition of respiration and glycolysis. The R.Q. was always lowered from about 0.86 to about 0.70 (averages of 7 experiments). Experiments showed that even in the presence of glucose, the dye at this concentration produced a progressive inhibition of the metabolism of tumour slices. In the first 20 min. there may have been acceleration, but after 45 min. there was very considerable inhibition. With tumour in the absence of glucose, and with other tissues with or without glucose, the inhibition must have set in almost immediately.

*Other oxidation-reduction dyes in high concentration.*

The dyes used for these experiments were the products of various firms<sup>1</sup> and, with the exception of prune, were not specially purified. Prune was purified by the salting-out method of Melville and Richardson [1934]. Since the initial experiments with 2:6-dichlorophenolindophenol were made at a concentration of  $1.3 \times 10^{-3} M$ , roughly this concentration was used for all the dyes. Usually a solution or suspension of 12 times this strength was prepared in Krebs medium, and 0.25 ml. was pipetted into 2.75 ml. of medium in the manometer vessels. In many cases, the dyes were not very soluble, or, as with Bindschedler's green and cresyl violet, they precipitated out in strong solution in the bicarbonate-containing medium. In such cases, the dye was added as a fine suspension, which usually became clear on dilution and at 37°. In nearly all cases, the tissue slices absorbed the dye so that they became more deeply stained than the medium: it was thus impossible to say what was the effective concentration of the dyes within the tissue. For experiments in the previous section, the 2:6-dichlorophenolindophenol solution was adjusted to  $1.3 \times 10^{-3} M$  after titration with ascorbic acid. In preparing solutions of this dye, much sparingly soluble material was removed by filtration so that the solution used, being fairly pure, actually may have been of a higher effective concentration than the unpurified suspensions or solutions of the other dyes used. The small inhibition of tumour respiration with glucose and of liver respiration mentioned in the previous section seems to have been determined by the higher dye concentration, and in the experiments shown in this section where one-third of this concentration is used, the results are entirely similar to those obtained with the other dyes.

<sup>1</sup> The dyes used were the products of the following firms:

Eastman Kodak Company: 2:6-dibromophenolindo-*m*-bromophenol (sodium 2:6-dibromobenzenone-indo-2'-bromophenol); *o*-chlorophenolindophenol (sodium benzenone-indo-3'-chlorophenol); 2:6-dichlorophenolindophenol (sodium 2:6-dichlorobenzenone-indophenol); 4:6-dinitro-*o*-cresol (3:5-dinitro-*o*-cresol).

British Drug Houses: Bindschedler's green; *m*-toluylenediamine-indophenol (*m*-tolylene-diamine-indophenol).

Le Motte: 1-naphthol-2-sulfonate-indophenol, K<sub>1</sub> indigotetrasulphonate, K<sub>2</sub> indigodisulphonate (Indigo carmine).

Coleman, Bell and Co.: Thionine.

Ciba and Co.: Prune.

E. Merck (Darmstadt): Methylene blue (chemically pure, zinc chloride-free).

National Aniline and Chemical Co.: Nile blue A, cresyl violet.

In Tables I–III the effects of the various dyes in a concentration of approximately  $10^{-3} M$  on tumour, brain, testis, retina, kidney and liver tissues in the presence and absence of glucose are shown. The dye solutions were always freshly prepared before use. The experimental period was in all cases one hour.

§ Melville and Richardson [1934].

|| Wurmser [1930].

The one effect that is common to all the dyes tried with tumour is that when a dye is in the medium the respiration is greater in the presence of glucose than in its absence, although normally the presence of glucose has little effect on the oxygen uptake of tumours [see Elliott and Baker, 1935]. With the series from *o*-chlorophenolindophenol to cresyl violet this contrast is strong, since all these dyes accelerate the respiration in the presence of glucose, and with the exception of cresyl violet which has the lowest  $E_0'$ , inhibit the respiration in the absence of glucose. There is often considerable variation between the results of similar experiments with slices from different tumours. Nevertheless, the qualitative effects of this series of dyes on the  $O_2$  uptake are fairly uniform. In their effects on glycolysis the results are very variable, but an increased glycolysis is often observed, and this was consistently found with the thiazine and oxazine dyes, namely, thionine, prune, methylene blue and cresyl violet. Elliott, Benoy and Baker [1935] noted some variation in glycolysis even between slices of the same tumour in normal conditions. The effects of the dyes on the

respiratory quotient in the presence of glucose are also variable but, in general, the R.Q. is lowered. The values for the R.Q. in the absence of glucose are not given since the inhibition then occurring leaves the residual respiratory exchange too small for accurate measurement.

Experiments with three other dyes,  $K_4$  indigotetrasulphonate ( $E'_0 = -0.046$ ),  $K_2$  indigodisulphonate ( $E'_0 = -0.125$ ), and Nile blue A ( $E'_0 = -0.122$ ) were made, since their potentials [Cohen, 1933] lie between those of methylene blue and cresyl violet. None of these three substances, however, had any appreciable effect on the respiration or glycolysis in the presence or absence of glucose. The ineffectiveness of the two highly sulphonated indigo dyes is probably due to their failure to penetrate into the cells [Chambers *et al.*, 1931]. (It was noticed that the tissues did not become noticeably stained in the presence of these dyes.) Although Nile blue penetrates well and stains the tissues, the colloidal nature of this dye perhaps prevents its access to the active centres reached by other dyes.

There is an indication of a grading of the effects of the dyes on the respiration of tumour dependent on their oxidation-reduction potentials. Dyes more positive than *o*-chlorophenolindophenol inhibit the respiration somewhat even in the presence of glucose; dyes in the main group accelerate the respiration in the presence of glucose and inhibit it in its absence, and cresyl violet, at the negative end of the series, accelerates in the presence of glucose but does not inhibit the respiration appreciably in the absence of glucose.

Results of Friedheim [1934] with pyocyanine are in quite good agreement with those in Tables I and II. Friedheim, using a  $2 \times 10^{-3} M$  solution of pyocyanine in Ringer solution, found that there was a large increase in the respiration of various tumours in the presence of glucose and very little effect in its absence, and that the aerobic glycolysis was considerably inhibited. In its effect on respiration, then, pyocyanine behaves like cresyl violet towards tumour and this is in accord with its low oxidation-reduction potential ( $E'_0 = -0.035 \pm$ ) [Michaelis *et al.*, 1932]. In its inhibitory effect on the glycolysis, it behaves differently from cresyl violet and the azine dyes.

The inhibitory effect of the dyes on the respiration in the absence of glucose appears to be largely reversible. An experiment with *m*-toluylenediamine-indophenol showed a 69% acceleration of respiration when glucose was present from the start; when samples of tissue from the same tumour were kept without glucose at 37° in the presence of the dye for 6 min. and for 20 min., and then glucose added, the subsequent respiration rates showed accelerations of 43 and 30% respectively. A similar result was obtained in a corresponding experiment with 1-naphthol-2-sulphonate-indophenol.

Included in Table I are results of experiments with 4:6-dinitro-*o*-cresol. As with the other dyes, the respiration is greater in the presence of glucose than in its absence. However, dinitrocresol does not behave as an ordinary reversible dye [Greville and Stern, 1935], and it does not fall into any of the above groups. There is some inhibition of respiration, even with glucose, accompanied by increased glycolysis, and the R.Q. is raised.

Table II shows the effects of various dyes at a concentration of  $10^{-3} M$  on the metabolism of brain, testis, retina and kidney. The most obvious effect is the large inhibition of the respiration of all these tissues even in the presence of glucose. These tissues, in fact, behave as does tumour tissue in the absence of glucose. With cresyl violet there is in several cases little effect, and this result was also obtained with tumour in the absence of glucose. Friedheim [1934] found that pyocyanine, which, like cresyl violet, has a negative  $E'_0$ , also had

The term  $Q_A^{O_2}$  represents the aerobic acid formation or glycolysis in terms of  $\mu$ l. of  $(CO_2)$  liberated from the bicarbonate in the medium per hour, per mg. dry weight of tissue.

\* Experimental period 2 hours.

little effect on kidney tissue in carbonate-Ringer solution (although in the presence of phosphate there was some acceleration); however, his finding that pyocyanine in  $2 \times 10^{-3}$  M concentration increased the respiration of testis in carbonate-Ringer solution indicates that the action of this pigment is not quite similar to that of cresyl violet. It will be noticed that cresyl violet and especially 4:6-dinitro-*o*-cresol increase the aerobic glycolysis of brain and testis considerably, the increases being relatively greater than those obtained with tumour. Indigodisulphonate was tried with kidney tissue, but, as with tumour, this dye neither stains the tissue nor affects its metabolism appreciably.

Table III shows the effects of a few dyes on liver metabolism. It is seen that an increase in respiration was obtained both in the presence and the absence of

glucose with the reversible dyes, but that there was inhibition with the dinitro-cresol. Liver thus behaves in the presence or absence of glucose as does tumour tissue in the presence of glucose.

*Effects of dyes in low concentrations.*

Most of the work done by other authors on the effects of dyes on tissue respiration has been with very low concentrations of the dyes. Barron [1930, 1] found no effect or a decrease in the respiration of kidney, testis and liver, and an increase with brain and tumours, using methylene blue at a concentration of 0.005–0.0005% (about  $10^{-4}$  to  $10^{-5} M$ ) in phosphate-Ringer solution. Himwich *et al.* [1933] found a decrease in respiration of brain tissue under similar conditions. Jares [1935], with 0.01% ( $3 \times 10^{-4} M$ ) methylene blue in phosphate-Ringer solution, found that the  $O_2$  uptake of a number of tissues was accelerated during the first 20 min., but that after 80 min. an inhibition had usually set in, while with tumour tissue the acceleration continued for a longer time. In Table IV, the results of a few experiments with dyes at  $10^{-5} M$  concentration

\* The respiration of brain in the absence of glucose is normally very low.

(0.0003%  $\pm$ ) are shown. These figures represent the average effects over the 60-min. experimental period, and with respect to methylene blue effects, they are probably about what might be expected from Jares's observations. In general, the effects of the dyes are less marked in the low concentrations than in the high, and there are no marked or constant effects on the glycolysis; often a small acceleration of  $O_2$  uptake is found instead of the inhibition found at the higher dye concentration. 4:6-Dinitro-o-cresol, however, increased the respiration and glycolysis of tumour, brain and liver tissue quite distinctly, and raised the R.Q.; this result is in agreement with the findings of Dodds and Greville [1934] with Jensen rat sarcoma. Dodds and Greville [1933] found the respiration of kidney tissue to be greatly increased by the dinitrocresol in lactate-containing phosphate medium, and they also reported an acceleration in the presence of glucose in

bicarbonate-containing medium but not in phosphate solution. In one experiment with glucose, shown in Table IV, no effect on the respiration rate of kidney tissue was observed, the medium containing bicarbonate as usual. The varying results of Dodds and Greville in the two media may have been due to chance variations in the tissues used.

Dickens [1934], who showed that thionine in  $5 \times 10^{-5} M$  concentration produced a large acceleration of kidney respiration in lactate-containing medium, also mentioned an increased respiration of kidney and Jensen rat sarcoma in glucose-containing medium. This observation with thionine on kidney is similar to the result in Table IV with methylene blue: Philadelphia No. 1 sarcoma tissue, however, in the presence of glucose with thionine or methylene blue ( $10^{-5} M$ ) did not show such acceleration. This disagreement may be due to the different tumours used or possibly to the somewhat higher dye concentration used by Dickens.

#### DISCUSSION.

The chief point of interest in the above results is the difference in the effects of dyes on the  $O_2$  uptake of tumour tissue depending on the presence or absence of glucose. The effects on the respiration caused by dyes in the main group in Table I in  $10^{-3} M$  concentration seem to divide the tissues studied into the following three groups:

(1) *Brain, testis, kidney, retina.*  $O_2$  uptake inhibited in the presence or absence of glucose.

(2) *Tumour.*  $O_2$  uptake inhibited in the absence of glucose and accelerated in its presence.

(3) *Liver.*  $O_2$  uptake accelerated in the presence or absence of glucose.

Judging from results obtained with dyes in low concentration and from those given by Jares [1935] for methylene blue, it would seem that all these reversibly oxidised substances are capable, under suitable conditions, of accelerating the respiration of tissues in general. As has been suggested by Barron [1930, 2], this is probably due to their ability to be reduced by various mechanisms in the cell and re-oxidised by atmospheric oxygen, so that they provide an alternative oxygen-activating mechanism. Besides this catalytic property, the dyes also seem to have a progressive poisoning effect as was made clear for methylene blue by Jares, and as is also shown even by tumour tissue *plus* glucose with strong 2:6-dichlorophenolindophenol. Such a combination of catalytic acceleration and progressive toxic inhibition of oxidative processes by dyes has been observed by Quastel and Wheatley [1931] in minced muscle.

When the concentration of the dyes is increased to  $10^{-3} M$ , the poisoning effect on tumour without glucose, and on brain, testis, kidney and retina with or without glucose, appears to be so rapid that the respiration is inhibited almost immediately. The various tables show that with all the tissues examined except liver, there is a tendency for the respiration to be more strongly inhibited by the dyes in the absence of glucose than in its presence, but the effect is much more marked with tumour, the respiration of which is, in the presence of glucose, actually accelerated by most of the dyes. It is not possible at this stage to explain this unique acceleration of tumour respiration. It may be that intermediate products of glycolysis in tumour are able to counteract the dye reactions which ordinarily inhibit respiration. More probably, such intermediate products are oxidised under the catalysis of the dyes; Barron and Harrop [1928] offered a similar explanation for results obtained with mammalian red blood cells and dilute methylene blue. The reason for the special position of liver is quite

obscure, though it might be expected that the behaviour of this tissue would be independent of glucose, since its normal  $O_2$  uptake, R.Q. and glycolysis are not affected by the presence or absence of glucose [Dickens and Greville, 1933; Elliott and Baker, 1935].

The effects of the dyes on glycolysis are also interesting, but again difficult to explain. Bumm *et al.* [1934] have brought forward and summarised evidence that respiration and glycolysis are not directly connected with each other, and they maintain that the principle of the Pasteur reaction, coupling increased  $O_2$  uptake with decreased fermentation, does not apply to most tissues. The effects shown in Table I provide further evidence against this principle since large increases in respiration are accompanied in some cases by no change in glycolysis and in some cases by considerable increases in glycolysis. According to the Embden-Meyerhof scheme [Meyerhof, 1935], there are stages in the glycolytic process which involve the reduction of one compound at the expense of the oxidation of another. At steps such as this, it is possible that certain reversibly oxidisable substances could act as catalysts, provided that their oxidation-reduction potentials and their chemical nature were suitable. In this way, the accelerating effects of methylene blue, thionine, prune and cresyl violet on tumour glycolysis might be explained. Lipmann showed that the glycolytic mechanism of muscle extract [1933] and the fermentation by yeast juice [1934] can be inhibited by oxidising agents or by dyes with high oxidation-reduction potential in the presence of oxygen. The converse effect, namely, acceleration of glycolysis by dyes of low oxidation-reduction potential in the presence of the reducing systems of the tissues, might then be expected. This seems to be realised in the marked increase in aerobic glycolysis of tumour and brain tissues produced by  $10^{-5}M$  phenosafranine ( $E'_0 = -0.25$ ) [Cohen, 1933] which was observed by Dickens [1935], and by the fact that cresyl violet ( $E'_0 = -0.167$ ), especially in the higher concentration, and also methylene blue, increase the glycolysis of tumour, brain and testis.

Though 4:6-dinitro-*o*-cresol in low concentration markedly accelerates the respiration of tumour, brain and liver, its toxic effect in the higher concentration used is so great that the oxygen uptakes of liver and of tumour even with glucose are inhibited. As with other dyes, however, the inhibition is greater with other tissues and with tumour in the absence of glucose. The most interesting effect shown here with the dinitrophenol in high concentration is the very large acceleration it produces in the glycolysis of brain, testis and liver as well as of tumour; from this and the fact that in general its presence causes a rise in the R.Q. toward the level required for carbohydrate oxidation, it seems that 4:6-dinitro-*o*-cresol in particular exerts its main catalytic effect on the carbohydrate metabolism.

#### SUMMARY.

1. 2:6-Dichlorophenolindophenol in  $1.3 \times 10^{-3}M$  concentration produces almost complete inhibition of the respiration of tumour tissue in the absence of glucose, and of kidney, brain, testis, retina and chick embryo in the presence or absence of glucose. Liver respiration is also considerably inhibited in either case, and its R.Q. is lowered. Tumour tissue alone, in the presence of glucose, continues to respire, although there is a progressive inhibition.
2. 2:6-Dichlorophenolindophenol in one-third of the above concentration, and a number of other oxidation-reduction potential indicator dyes in approximately  $10^{-3}M$  concentration, accelerate the respiration of tumour tissue in the presence of glucose and inhibit it in the absence of glucose. In this concen-

tration, these dyes produce considerable inhibition of respiration with brain, testis, kidney and retina, even in the presence of glucose. The respiration of liver tissue is accelerated in the presence or absence of glucose.

3. Thionine, prune, methylene blue and cresyl violet in  $10^{-3}M$  concentration, besides accelerating the respiration of tumour slices in glucose medium, also increase the aerobic glycolysis. Cresyl violet also increases the glycolysis of brain and testis somewhat.

4. In  $10^{-5}M$  concentration the effects of the dyes are less marked. With all the tissues tried there is usually a slight increase in the average rate of respiration in the presence of glucose over a 60-minute experimental period and some inhibition in the absence of glucose.

5. In  $10^{-3}M$  concentration, 4:6-dinitro-*o*-cresol increases the glycolysis of tumour tissue and of brain, liver and testis. It inhibits the respiration of liver and of tumour tissue somewhat even in the presence of glucose. As with the other dyes, there is a large inhibition of the respiration of tumour tissue in the absence of glucose and of other tissues in the presence or absence of glucose. In  $10^{-5}M$  concentration, 4:6-dinitro-*o*-cresol accelerates the respiration of tumour, brain and liver tissues considerably.

# CCLXXXV. GLUTATHIONE AND ASCORBIC ACID IN TISSUES OF NORMAL AND TUMOUR- BEARING ALBINO RATS.

By GLADYS ESTELLE WOODWARD.

*From the Cancer Research Laboratories, Graduate School of Medicine,  
University of Pennsylvania, Philadelphia, Pa.*

*(Received July 6th, 1935.)*

A POWERFUL reducing substance giving the indophenol reaction for ascorbic acid was shown by Birch and Dann [1933] to be present in a wide variety of animal tissues in amount comparable with the glutathione present. It then became apparent that values for tissue glutathione determined by methods depending upon its reducing capacity might include both glutathione and ascorbic acid. In tumour tissue, using a colorimetric nitroprusside method, Boyland [1933] showed that only about one-third of the total iodine value was due to glutathione whilst the remainder could be accounted for by the indophenol titration as ascorbic acid. It should be pointed out however that it is not yet certain that the material in all tissues reacting in this method is actually ascorbic acid.

Recently the author [1935] has demonstrated a method which appears to be absolutely specific for glutathione. Using this method, which depends upon the degree of activation of glyoxalase by glutathione, further investigation has been made of the glutathione contents of tumour tissue and other tissues of the cancer-bearing animal along with ascorbic acid titrations of the same tissues. Since tumours contained a relatively high amount of this ascorbic acid-like material, experiments were likewise carried out to see whether the concentration of this substance could be changed experimentally in the animal with resultant effect upon growth of the tumours.

## METHODS.

*Animals.* Albino rats of the Germantown strain, covering a weight range of 75–250 g., were used. The tumour-bearing animals had received transplanted tumours of the Philadelphia No. 1 sarcoma and Walker No. 256 carcinoma strains. A histological description of these tumours has been given by Waldschmidt-Leitz *et al.* [1933]. The rats were fed on a standard diet consisting of corn, oats, bread and lettuce.

*Tissue extracts.* These were prepared by a method similar to that proposed by Okuda and Ogawa [1933]. The tissues were removed immediately from the stunned and decapitated animal. After weighing each tissue, it was placed in a mortar, covered by one volume of 0.25 *M* salicylsulphonic acid and then ground in the absence of sand or other extraneous agent. The tissue readily disintegrated to a fine pulp. The pulp was then washed into a graduated cylinder or tube by means of 0.125 *M* salicylsulphonic acid and made up to a volume corresponding to five times the weight of the tissue used, or 1:5 dilution. In the case of liver, a 1:10 filtrate was used, making up to volume with 0.1 *M* salicylsulphonic acid instead of 0.125 *M*. In the case of adrenal, where only 20–30 mg. were available per animal, a 1:50 filtrate was used. The adrenals were ground with 0.3 ml. of

0.1 *M* salicylsulphonic acid and made up to volume with the same strength acid. With the last two tissues, where deviation was made from the usual 1:5 dilution, the strength of acid used had to be varied as indicated in order to bring the resulting filtrates to the same degree of acidity. After standing for about 15 min. and thorough mixing, the extracts were filtered through Whatman No. 30 filter-paper.

*Glutathione estimation.* The manometric glyoxalase method previously described by the author [1935] was used throughout.

*Ascorbic acid estimation.* This was based upon the principle of Birch *et al.* [1933] of addition of the ascorbic acid solution to a definite amount of standardised 2:6-dichlorophenolindophenol. In these experiments however the salicylsulphonic acid extracts of the tissues were used instead of trichloroacetic acid extracts. The superiority of the former acid for indophenol titrations of ascorbic acid was pointed out in the previous paper [Woodward, 1935].

### EXPERIMENTAL.

#### *Normal animals.*

The values for normal animals, fasting 24 hours, are given in Table I. A few values were also determined on animals not fasting. The only differences observed were in the liver and kidney glutathione values, which were higher in the non-fasting animals. It was also noted that the ascorbic acid value remained constant for a much longer time in the case of the filtrates from the fasting animals. Only the fasting values were used therefore for comparisons. In some of the tissues studied, there seems to be a surprisingly small range of values. This is particularly true of the glutathione in adrenal, kidney and spleen, and the ascorbic acid in liver and kidney.

#### *Tumour-bearing animals, untreated.*

Table II gives the results on rats with Walker No. 256 carcinoma and with Philadelphia No. 1 sarcoma. Both tumours were found to contain large amounts of glutathione and of a material which titrates as ascorbic acid. The concentration of the latter is higher in tumour tissue than in any other tissue studied with the exception of adrenal. Brain and thymus were investigated in a few cases and found to contain amounts of ascorbic acid in the vicinity of 35 mg. per 100 g. each, the glutathione amounting to 45 and 50 mg. per 100 g. respectively. In no tissue does there seem to be a significant increase or decrease in the concentration of either glutathione or ascorbic acid when the tumour-bearing animals are compared with the normals.

Average						82	88	134	70	90	65	403	21	16	30

A characteristic difference between the two tumours studied is noted in the relative glutathione and ascorbic acid contents of each. The Walker No. 256 carcinoma is characterised by a higher glutathione content and a lower ascorbic acid content than the Philadelphia No. 1 sarcoma. Thus the ratio of glutathione to ascorbic acid in the carcinoma is usually over 1.6 with an average of 1.9, whilst in the sarcoma it is usually under 1.4 with an average of 1.3.

It should be pointed out that the above-mentioned figures for tumour tissue were obtained only on that part of the tumour which was healthy growing tissue. Comparative analyses on necrotic parts from some of the tumours, Table III,

 Table III. *Comparison of healthy and necrotic tumour tissue.*

	Glutathione		Ascorbic acid	
	Healthy mg./100 g.	Necrotic mg./100 g.	Healthy mg./100 g.	Necrotic mg./100 g.

	82	8	45	9
Walker No. 256 carcinoma	76	12	25	5

showed a very small amount of both reducing substances in these areas. Since it is not possible entirely to separate the growing cells from the necrotic, it seems quite probable that, in purely necrotic cells, none of either of the reducing materials is present. Edlbacher and Jung [1934] had previously reported that ascorbic acid was 10 times lower in necrotic tissue of Jensen rat sarcoma, and that the total iodine value, representing both glutathione and ascorbic acid, was 4-5 times lower. The fact that these materials are non-existent or low in necrotic tissue may explain discrepancies which have been reported in the literature with regard to the ascorbic acid value and particularly the glutathione content of tumours. It has been the experience of the author that in the Ehrlich mouse carcinoma the necrotic cells are scattered throughout to such an extent that it is practically impossible to obtain a representative sample of healthy tissue for analysis. This probably accounts for the fact that the values for

0.1 *M* salicysulphonic acid and made up to volume with the same strength acid. With the last two tissues, where deviation was made from the usual 1:5 dilution, the strength of acid used had to be varied as indicated in order to bring the resulting filtrates to the same degree of acidity. After standing for about 15 min. and thorough mixing, the extracts were filtered through Whatman No. 30 filter-paper.

showed a very small amount of both reducing substances in these areas. Since it is not possible entirely to separate the growing cells from the necrotic, it seems quite probable that, in purely necrotic cells, none of either of the reducing materials is present. Edlbacher and Jung [1934] had previously reported that ascorbic acid was 10 times lower in necrotic tissue of Jensen rat sarcoma, and that the total iodine value, representing both glutathione and ascorbic acid, was 4-5 times lower. The fact that these materials are non-existent or low in necrotic tissue may explain discrepancies which have been reported in the literature with regard to the ascorbic acid value and particularly the glutathione content of tumours. It has been the experience of the author that in the Ehrlich mouse carcinoma the necrotic cells are scattered throughout to such an extent that it is practically impossible to obtain a representative sample of healthy tissue for analysis. This probably accounts for the fact that the values for

Ehrlich carcinoma are lower than those for the other two tumours. Analyses on the best material available gave for glutathione 22, 30 and 43 mg. per 100 g. and for ascorbic acid 9, 13 and 11 mg. per 100 g. Similar values for ascorbic acid in this tumour were reported by Galigani [1934].

*Tumour-bearing animals, treated with ascorbic acid.*

An extremely large stimulation of tumour growth has been reported by Fodor and Kunos [1934] in mice with Ehrlich carcinoma which were fed or injected with ascorbic acid. An attempt to duplicate their results with a series of animals injected subcutaneously has failed here. There was no increased growth of the tumours. On the whole the growth of these tumours was so erratic even in the controls as to allow of no definite conclusions. The experiment was therefore repeated on a series of rats with Walker No. 256 carcinoma and with Philadelphia No. 1 sarcoma. With both these tumours the rates of growth were practically the same as in the controls. At the end of the experiment, the tissues were subjected to the same analyses as those of the untreated tumour-bearing animals. The results, Table IV, show that the ascorbic acid concentration has not been significantly increased in any tissue with the possible exception of tumour tissue, and here the significance of the apparent slight increase is doubtful.

\* In the carcinoma group, rats Nos. 1, 2 and 3 had received subcutaneously 0.5 ml. containing 10 mg. for 8, 10 and 11 days respectively; Nos. 4, 5 and 6, 0.5 ml. containing 20 mg. for 10, 11 and 12 days respectively.

In the sarcoma group, rats Nos. 1 and 2 had received subcutaneously 0.6 ml. containing 4.5 mg. for 11 and 25 days respectively; Nos. 3, 4 and 5 had received 0.5 ml. containing 10 mg. for 16, 14 and 20 days respectively.

All analyses were made 24 hours after the last injection.

*Tumour-bearing animals, treated with mannose and glucose.*

The origin of ascorbic acid in plant tissues was investigated by Ray [1934] whose results indicated that ascorbic acid could be formed naturally from the hexoses, particularly mannose. The association of mannose in plant tissues rich in ascorbic acid had previously been noted by Euler and Klusmann [1933, 1]. Evidence was also offered [Guha and Ghosh, 1934] that mannose, alone among the sugars, could be converted into ascorbic acid *in vitro* by certain tissues of the rat. As a substance which might possibly be transformed into ascorbic acid by tumours *in vivo* and thus stimulate their growth, mannose was injected

subcutaneously into a series of tumour-bearing rats. From analyses of tissues of rats under such treatment, Table V, it is seen that no such synthesis occurred. Neither the concentration of ascorbic acid in the tumours and other tissues nor the rate of growth of the tumours was affected in any way.

Rats with Philadelphia No. 1 sarcoma were likewise treated with glucose without any effect upon the tumours or other tissues (see Table VI).

Table V. *Tumour-bearing rats after mannose injections.\**

\* All the rats received subcutaneously 1 ml. 50% glucose twice daily for the first 11 days, then 1 ml. daily for 14, 21, 27 and 28 days respectively. Analyses were made 24 hours after the last injection.

#### *Tumour-bearing animals, treated with oxidation-reduction dyes.*

In an attempt to decrease the ascorbic acid content of the tumours, tumour-bearing animals have been injected with oxidation-reduction dyes known to react with ascorbic acid, that is, dyes with a more positive potential than that of ascorbic acid. 2:6-Dichlorophenolindophenol, toluylene blue and the dye prune have been used in a series of 10 rats for each dye with tumours about 0.5 cm. in diameter, half of each group receiving the dye subcutaneously near the site of the tumours and half into the tumours. There was no marked difference in the growth of any of the tumours as compared with a control group. The tumours which had been injected with prune were however among the largest developed. Analyses of a few of the tissues are reported in Table VII. Here also there has been no definite effect on the concentrations of ascorbic acid and glutathione in the tumour or other tissues. Euler and Klusmann [1933, 2] had been able to reduce the ascorbic acid content of guinea-pig adrenal by half in

4 hours by a single subcutaneous injection of methylene blue, but it must be borne in mind that guinea-pig tissues are much more susceptible to vitamin C (ascorbic acid) variations than rat tissues.

\* 0.2 ml. 0.1% dye daily at first, increasing to 0.4 ml. as the tumours became larger. Analyses were made 24 hours after the last injection.

The question also arises as to whether the dyes were able to penetrate into the tumour cells. Prune and the indophenol in their oxidised (coloured) forms were quite apparent in the necrotic areas of the tumours where the analytical figures have shown a lack of reducing substances. In the healthy growing parts of the tumours no evidence was found that any dye, even in its reduced (colourless) form, was present, for, when tissue slices or tissue extracts were treated with ferricyanide or with hydrogen peroxide, no colour developed. It is therefore possible that the dyes did not penetrate into the tumour cells and for this reason could not react with the ascorbic acid present.

#### *Tumour-bearing animals treated with X-rays.*

Having failed to change materially the concentration of ascorbic acid or glutathione in tumours by any of the injection experiments, it was thought of interest to investigate the concentration of these substances in a tumour whose growth had been checked by X-rays. Such tumours were kindly supplied by Dr George Bancroft of this laboratory. Using twin tumours on a rat and applying X-rays to one tumour, the other being shielded, he had been able to produce varying degrees of retardation of growth in the treated tumour as compared with the control tumour on the same rat. Analyses of such pairs of tumours are recorded in Table VIII. Where the X-ray treatment was effective, a distinct diminution of glutathione in the tumours was found (Nos. 3, 4, 5, 9, 10 and 11). Ascorbic acid was likewise distinctly decreased in the Philadelphia No. 1 sarcomas, but not in the Walker No. 256 carcinomas. In tumours resistant to X-rays, the decreases in these values were not noted (Nos. 6 and 7). Furthermore, in a tumour which had started to grow again after X-ray treatments were stopped (No. 8), both reducing substances were found in an amount as high as in the control tumour.

It seems very likely that the decreased glutathione content found in X-ray-treated tumours is not a direct effect of the X-rays on glutathione since it was shown by the author [1933] that glutathione is extremely resistant to large doses of X-rays. These doses were 7–10 times larger than those applied to the rat tumours by Dr Bancroft. It has however been shown by Kinsey [1935] using softer X-rays than those used in this laboratory that glutathione in pure solution

may be somewhat destroyed. The decrease in glutathione may find an explanation as a secondary effect, being an expression of the reduced metabolism of the treated tumours.

#### SUMMARY.

1. Walker No. 256 carcinoma and Philadelphia No. 1 sarcoma were found to contain glutathione in amount comparable with other body tissues of the rat and ascorbic acid-like material in amount higher than any other tissue studied except adrenal. These reducing substances were present only in the growing parts of the tumour, there being practically none in the necrotic part. Ehrlich mouse carcinoma is too necrotic throughout to make a good separation and values obtained with this tumour are therefore low. Glutathione is slightly higher in the carcinoma than in the sarcoma, whilst ascorbic acid is somewhat lower in the former. Thus the ratio of glutathione to ascorbic acid in the carcinoma is usually over 1.6 and in the sarcoma under 1.4.

2. Corresponding tissues in the normal and tumour-bearing rats showed no significant differences in their glutathione and ascorbic acid contents.

3. Long-continued injections of ascorbic acid, mannose, glucose or oxidation-reduction dyes into tumour-bearing rats did not materially affect the concentrations of ascorbic acid or glutathione in the tumour tissue or other tissues of the body. The growth of the tumours was likewise not affected.

4. X-ray treatment caused a decrease in the glutathione values of the tumours provided that the treatment was effective in retarding the growth of the tumours; the ascorbic acid value was reduced only in the Philadelphia No. 1 sarcoma. In tumours resistant to X-rays, no decrease in the values was noted.

The author wishes to acknowledge the assistance of Miss Mary A. Russell in the treatment of the animals.

# CCLXXXVI. PHYSICAL CHEMISTRY OF LIPOIDS.

## III. RELATIONS BETWEEN THE IODINE VALUE OF MONOPHOSPHATIDES AND THEIR REACTIONS TO NEUTRAL SALTS.

By MONA SPIEGEL-ADOLF.

*From the Department of Colloid Chemistry, D. J. McCarthy Foundation,  
Temple University, School of Medicine, Philadelphia, Pa.*

*(Received June 24th, 1935.)*

It has been reported in a previous communication [Spiegel-Adolf, 1932, 1] that, contrary to the Hofmeister series, colloidal solutions of egg-lecithin show a greater decrease in viscosity on addition of bromides than on addition of chlorides, iodides and thiocyanates. These results combined with more recent interferometric studies [Spiegel-Adolf, 1932, 2] were explained as due to reaction of molecular bromine with the unsaturated groups of the lecithin molecules. The experiments to be reported here were started with the aim of verifying this theory. As the number of unsaturated groups can be measured by their power to add iodine, determinations of the iodine value for the material under physico-chemical investigation were started.

These experiments of Spiegel-Adolf [1932, 1, 2] had been made on egg-lecithin (Merck). Therefore we first determined the iodine value in a colloidal solution of egg-lecithin, as we could not find references to the iodine value of colloidal lecithin. In order to exclude the factor of ageing [Spiegel-Adolf, 1932, 1], a two months-old lecithin sol was used, made in the way previously [Spiegel-Adolf, 1932, 2] described. The determinations of the iodine value were made according to Hübl [1924], after the lecithin had been precipitated by a mixture of  $\text{CaCl}_2$ ,  $\text{MgCl}_2$  and  $\text{HCl}$ .

The result was an iodine value of 41. Levene and Rolf [1926] obtained 47 as the iodine value for a lecithin made from egg-yolk by precipitation with a cadmium salt.

In order to test further the supposed relation between iodine value and reactions to bromides different ways were tried of modifying the iodine value.

1. Irradiation by ultraviolet light is known to decrease the iodine value of lecithin. By exposing samples of 1% lecithin sol in quartz tubes for 4 hours at a distance of 40 cm. to the irradiation of a mercury quartz lamp (Hanovia, 220 V, D.C.), it was possible to reduce the iodine value in another sample from 35 to 30. The viscosity showed a slight increase, thus confirming findings of Nagata [1930].

A shorter period of irradiation has a lowering influence on the viscosity of the lecithin sol. But whilst with the non-irradiated sample, as has been previously shown [Spiegel-Adolf, 1932, 1], bromide caused a sharper decline of the viscosity than did chloride, the difference disappeared completely with the irradiated sample. Table I shows the values for a typical experiment.

Table I.

Salt	Viscosity (measured in sec./5)			Iodine value
	None	KCl	KBr	
Non-irradiated lecithin	1261	1075	1069	35
Irradiated lecithin	1276	1090	1090	30
Biochem. 1935 xxix	( 2413 )			154

2. A sample of egg-lecithin was iodinated to its maximum capacity, as for the determination of the iodine value. The chloroform was removed by evaporation, and the lecithin was washed till any increase in conductance of the wash water had disappeared. In a preliminary test it was ascertained that no further iodine could be added, the iodine value having become zero. It was possible to make a colloidal solution of this preparation, the viscosity of which was very low. The depressing effects of KCl and KBr were practically identical. Yet a higher concentration of KCl caused a still lower viscosity, showing that the lack of a specific effect of bromides on this sol was not due to the fact that the viscosity had already reached its lowest limit (Table II).

Table II. *Viscosity of iodinated lecithin sol.*

	Salt content			
	None	0.05 N KCl	0.05 N KBr	0.1 N KCl
Iodinated lecithin	869	863	864	859
Water	858	—	—	—

3. Two samples of lecithin and kephalin from human brains were available which had been oxidised in a non-evacuated desiccator. Their iodine values were 23 and 22.5 respectively. Levene and Rolf [1927] had found for brain lecithin an iodine value of 61. The reactions of colloidal solutions of these preparations with different salts as to viscosity and refractivity are summarised in Tables III and IV.

Table III.

	Viscosity (measured in secs./5)	Interferometric units		
		Measured	Calculated	Difference
0.5 % kephalin + 0.05 N KCl	899	354	358	4
0.5 % kephalin + 0.05 N KBr	900	407	412	5

Table IV.

Final kephalin concentration 1 %, final salt concentration 0.05 N. For interferometric measurements diluted with distilled water 4 times.

Salt	Viscosity			Interferometric units		
	I	II	III	Measured	Calculated	Difference
None	1062	1054	1014	109	—	—
KCl	1000	1012	975	141	141	0
KBr	1000	—	—	157	157	0
KI	1007	1021	—	195	194	-1
KCNS	1030	1046	1007	181	179	-2
KI + I <sub>2</sub>	—	1078	—	—	—	—

These results show no special effect of bromides either on viscosity or on refractivity, but they do show the validity of the Hofmeister series. Yet only the reaction of human brain lecithin can be used as further confirmation of the above-mentioned theory. Only lecithin sol shows a further drop in viscosity on addition of a mixture of KI + I<sub>2</sub> as does the egg-lecithin sol (Table V); kephalin sol, on the contrary, shows an absolute rise in viscosity.

As both lecithin and kephalin contain unsaturated fatty acids, the difference in their behaviours may be sought in their different degrees of hydration. In view of the recently suggested use of thiocyanates in brain diseases the figures should

Table V.

Final lecithin concentration 0.5 %, final salt concentration 0.05 N. For interferometric measurements 5 times diluted with distilled water.

Salt	Viscosity		Interferometric units		
	I	II	Measured	Calculated	Difference
	I	I	I	I	I
None	936		—	—	—
KCl	889	882	84	85	1
KBr	887	—	96	97	1
KI	—	880	—	—	—
KCNS	—	882	—	—	—
KI + I <sub>2</sub>	879	—	191	196	5

suggest some caution. The substitution of thiocyanates for chlorides may be followed by a swelling of the brain in which kephalin prevails quantitatively over lecithin [Singer, 1926].

## SUMMARY.

The experiments reported were made in order to test the previously assumed relation between the number of non-saturated groups in lecithin sol and its specific reaction to bromides. Therefore determinations of the iodine value were made on various samples of normal, irradiated and iodinated egg-lecithin, and on spontaneously oxidised human lecithin sol and kephalin sol. In the same samples the changes in viscosity and refraction upon addition of various salts were observed. A marked parallelism between a decrease of the iodine value and the disappearance of a specific effect of bromides was found.

# CCLXXXVII. THE EFFECT OF X-RAYS UPON THE METABOLISM AND GROWTH OF TRANSPLANTABLE TUMOURS.

By GEORGE BANCROFT, LYLE VIBERT BECK AND  
MARY ANNA RUSSELL.

*Cancer Research Laboratories, Graduate School of Medicine, University  
of Pennsylvania, Philadelphia, Pa.*

*(Received August 12th, 1935.)*

THE study of the primary action of X-rays upon tumour tissue *in vivo* has been handicapped by the inability to detect small differences in metabolism because of large variations from animal to animal. The small changes in metabolism that might indicate a primary effect of radiation could not be estimated from irradiation *in vivo*. Attempts have been made to avoid this difficulty: for example Crabtree [1933] found that continuous radiation with radium produced a lowering of the oxygen uptake by tumour slices before any effect on the aerobic glycolysis was evident. However, in living tissue such radiation may be largely effective through indirect means which could not be detected by such a method. We have found that the metabolisms of two tumours inoculated in similar situations into the same animal are very similar and do not show the variations characteristic of tumours in different animals. By shielding one tumour from the direct action of X-rays, it is possible to use this tumour as a control for the radiated one. This technique has made it possible to detect small characteristic changes in respiration and glycolysis caused by X-rays.

## EXPERIMENTAL.

Two transplantable rat tumours were used in these experiments; Philadelphia 1, a fibrotic sarcoma, and Walker 256, a rapidly growing cellular carcinoma. A complete histological description of these tumours has been given already by Waldschmidt-Leitz, McDonald and co-workers [1933]: both have been maintained in the laboratory over several years by reinoculation and have been found to be quite consistent in their characteristic growth and histological appearance. The tumour fragments used for inoculation were obtained under as nearly sterile conditions as possible immediately after the animal was killed by a blow on the head. The tumour was then transferred to a sterile Petri dish and moistened with Ringer solution and the healthy portions cut into fragments of appropriate size. For the double inoculations, these pieces were divided as nearly as possible into two equal cubes of 1–2 mm.<sup>3</sup> and inoculated with a trocar subcutaneously into both flanks after sterilising the skin with alcohol. It is important in this connection that the two pieces should be nearly identical as to size and quality of tissue in order that the tumours may grow at the same rate. Care should also be taken lest the tumour penetrate the body wall, since Crabtree [1929] has shown that the metabolism is much lower in such conditions than it is when inoculated subcutaneously. By inoculating fifteen animals, it was usually possible to get ten to twelve animals with two tumours that would grow at the same rate. Only male rats weighing 80–120 g., of the Germantown Albino strain, were used and they were fed on a standard diet consisting of lettuce, bread, a mixture of boiled

cereal grains and some milk. The Walker 256 tumours were large enough for measurement about 10 days after inoculation and the Philadelphia 1 tumours after about 17–20 days.

Each experimental animal was weighed and the approximate size of the tumour measured with calipers every 2–3 days for the Walker 256 and every 3–4 days for the Philadelphia 1, and drawings were made according to these measurements to record the growth. In order to facilitate the tabulation of these measurements, the area in  $\text{cm}^2$  was determined by means of a Keuffel and Esser planimeter. After several measurements to make sure that the two tumours were growing at approximately the same rate, the animals were subjected to treatment. If there was any slight difference in size of the two tumours, the larger one was always irradiated.

The strength of the X-rays used was measured during radiation by the usual ionisation chamber-galvanometer arrangement, the ionisation chamber having been calibrated previously with a standard ionisation chamber as described by Taylor and Singer [1930]. It was found after some experimentation that the total dose of X-rays given over varying periods of time was not as good a measure of the strength of the X-rays as the saturation method of measurement of Pfahler [1928]. This method depends upon the fact that the biological effects of each dose of X-rays decrease with time, the rate of decrease following a logarithmic curve. When applying successive doses, the average effectiveness over the period covered by the treatment is not equal to the sum of X-ray units actually applied, but to the average of the residual effects of the successive doses. For example, to maintain a level of X-rays of 400 R, 150 R units would be administered after the effectiveness of the preceding dose had dropped to 350 R. The loss of the effectiveness of the X-rays was calculated from the curve given by Pfahler for X-rays of 127 KV through 3 mm. of aluminium. For radiation, the rats were immobilised by wrapping in cheesecloth, fastened down to  $\frac{3}{4}$  inch boards of suitable size with drawing pins through the gauze and covered with heavy lead arches through which a hole had been cut slightly larger than the size of the tumour to be irradiated. The position of the animal was such that the control tumour was well protected by lead and only a small portion of the body of the rat was in the path of the X-ray beam through the radiated tumour. The calibration of the X-ray apparatus gave a factor of 1.59 R units per minute per cm. deflection of the galvanometer. Thus at a deflection of 20 cm. for 15 minutes the animal would receive  $1.59 \times 20 \times 15 = 477$  R units.

At the completion of the X-ray treatments, or after a suitable time, the rat was stunned by a blow on the head and bled from the neck and the tumours were removed and covered with Ringer-Locke solution. Slices were cut immediately for manometric determination of the oxygen uptake, *k*.q. and aerobic glycolysis of the two tumours in the Dixon-Keilin [1933] apparatus. The methods and precautions described by them as modified by Elliott and Schroeder [1934] were followed exactly. At the same time sections were taken from near the periphery to correspond as closely as possible with those used in the manometers for histological examination. These were fixed in Zenker's solution and then stained with haematoxylin and eosin. These sections after mounting were examined as to size and form of cells, relative abundance of tumour cells and the number of cells showing mitotic figures.

In order to check the metabolism of different tumours in the same animal a number of experiments were carried out with untreated animals. The results of these experiments with the Philadelphia 1 sarcoma and the Walker 256 carcinoma are given in Table I.

Table I. *Metabolism of sets of two tumours inoculated into each animal.*

		R.Q.		- $Q_{O_2}$		$Q_A$	
		Left	Right	Left	Right	Left	Right
Philadelphia 1	Without glucose	0.77	0.73	11.7	11.2	—	—
	Without glucose	0.85	0.81	10.6	10.6	—	—
	With glucose	0.86	0.83	10.2	10.4	20.6	20.2
Walker 256	With glucose	0.82	0.80	11.2	10.0	13.2	12.7
	With glucose	0.79	0.76	11.1	10.3	15.8	18.6

Elliott and Baker [1935] have shown that there may be an error of 0.03 in the R.Q. measurements so the agreement between the R.Q. measurements may be considered satisfactory. The determination of the aerobic glycolysis in twin tumours does not yield as close checks as the other measurements and indeed Elliott *et al.* [1935] have found it difficult to obtain close checks on the aerobic glycolysis even from slices taken from the same tumour.

### RESULTS.

In Table II, the effect of different levels of radiation upon the growth and metabolism of the Walker 256 carcinoma is shown. The effect of X-rays seems to be more or less proportional to the dose as calculated by Pfahler's saturation method. With the higher levels of X-ray, the effect is always a regression in the size of the tumour and a reduction in the oxygen uptake of the tissue with occasional effect upon the R.Q. but without any appreciable effect upon the aerobic glycolysis ( $Q_A$ ). These determinations with the higher levels of X-ray were made after considerable regression had taken place, so it is not possible to say whether the reduction in respiration caused the reduction in growth or *vice versa*. However, in view of Exps. 22 and 20 in which the rate of growth was affected without any significant changes in the metabolism, it seems probable that the lower oxygen uptake, observed in the other cases, was a result of the reduction in growth rather than a causative factor. The practically complete elimination of tumour cells as a result of the radiation in Exps. 25 and 35 with the extreme drop in the oxygen uptake as well as the loss of the power to glycolyse aerobically should be noted. The close agreement in the type and extent of the changes in the metabolism between Exps. 14 and 15 and between 20 and 22 when treated similarly even though not at the same time shows that it is possible to obtain consistent results if the conditions are maintained the same.

Although the number of experiments is not sufficient definitely to establish a regular sequence of events after irradiation, there seems to be a correlation between the effects on growth and the characteristic changes in the metabolism and histology of the tumours. The first histological effect of radiation observed in this work was a reduction in the number of mitoses which was often accompanied by incomplete cell division and the formation of large or giant cells. At the same time the growth of the radiated tumour was slowed up but without any consistent changes in the oxygen uptake or the aerobic glycolysis. A reduction in the number of tumour cells in any given area followed and was usually accompanied by cessation of growth and a small decrease in the oxygen uptake, the aerobic glycolysis remaining unaffected. During the last stage, the number of tumour cells was decreased further and an infiltration of connective tissue appeared which gradually smothered the remaining tumour cells. This was accompanied by a regression in the size of the tumour, a further reduction in the oxygen uptake and a gradual decrease in the aerobic glycolysis.

\* The average X-ray dose is the average effective amount of radiation as calculated from Pfahler's curves for maintaining a saturation dose, assuming that 100% saturation for 127 KV through 3 mm. of Al is 550 R. The numbers in parentheses indicate the sum of the individual doses of X-rays given to each animal.

† The number of tumour cells was determined by actual counts of 10 microscope fields taken at random from the stained sections and the number of mitoses from counts of 50 such fields.

‡ The figures in parentheses indicate the number of abnormal mitoses.

[illegible]

1 The radiated tumour contained mostly enlarged cells with much connective tissue.

<sup>2</sup> Some connective tissue was beginning to appear in the radiated tumour.

<sup>3</sup> Many of the irradiated tumour cells were enlarged.

4 The tumour cells were nearly all replaced by connective tissue.

<sup>5</sup> Necrosis made cell counts of doubtful value.

The amount of connective tissue present was increased.

7 Most of the cells were abnormal and the amount of connective tissue was greatly increased.

8 All the mitoses in the irradiated tumour were abnormal.

The connective tissue was increased and there were many somewhat enlarged cells.

\* The numbers in parentheses indicate the sum of the individual doses of X-ray administered to each animal.

In preliminary work, even high doses of X-rays failed to produce much effect upon the metabolism of the Philadelphia 1 sarcoma. Eichholtz *et al.* [1934] reported that subcutaneous injection of insulin seemed to increase the sensitivity of certain rat tumours to X-radiation, owing, he believed, to its effect upon the glycolysis. Since the aerobic glycolysis is practically unaffected by X-ray treatment until after considerable degeneration of the tissue has taken place, it seemed possible that the effect might be a result of changes in the blood sugar level which altered the amount of blood sugar available for tumour growth. A set of animals therefore was injected subcutaneously with one unit of insulin per kg. 2 hours before irradiation. A large number of blood sugar analyses were made, the blood being taken from the femoral artery by means of a small incision, but no consistent correlation was found between the blood sugar level and the sensitivity of the tumours towards irradiation, even though the amount of sugar was reduced considerably. Moreover, subcutaneous injections of adrenaline and glucose, which raised the blood sugar level enormously, did not decrease the sensitivity of the tumours. The results of irradiating the tumours of these two sets of animals as well as a set of untreated (normal) animals are summarised in Table III.

The effects of different levels of radiation upon the Philadelphia 1 tumour are rather variable although, in general, they are proportional to the dose of X-rays given. This variability may depend, in part, upon some unknown factor which influences the sensitivity. The differences in sensitivity towards radiation produced by the different treatments of the animals are not great, but the effect of radiation on the tumours may be slightly higher for the starved animals than for those treated with insulin, and slightly greater for the latter than for the normal animals.

The histological changes seem to follow the same course under the influence of X-rays as was shown with the Walker 256 carcinoma, but the results are more indefinite; the proportion of enlarged cells after irradiation is always smaller, the infiltration of connective tissue is less pronounced and a complete disappearance of tumour cells has never been observed so far even with heavy doses of X-rays.

The effect of X-rays upon the metabolism shows a small but fairly regular decrease in the oxygen uptake ( $Q_{O_2}$ ) but no significant change in the aerobic glycolysis except in the final stages of regression of the tumour. There is, however, an almost constant lowering of the R.Q. with the Philadelphia 1, which is also common with the Walker 256. In Table III there are only three apparent exceptions to this change in the R.Q. all of which are readily understandable. In Exps. 29 and 42 X-rays had no apparent effect either on the growth or on the metabolism so that no change in the R.Q. would be expected. The R.Q. of Exp. 23 was also normal, but since the histology showed that practically all the tumour cells had been replaced by connective tissue cells the comparison is really between the metabolisms of two different tissues and not between radiated and non-radiated tumour tissues.

#### DISCUSSION.

Warren [1928] states that the injury to cell structures of body tissues by radiation is roughly proportional to the amount of radiation administered, although the extent of the injury may vary with different tissues and different species. The effect of radiation upon mitoses and the formation of enlarged cells has been observed also by many workers (see, for example, Ludford [1932]). The infiltration of connective tissue, after radiation by radium has caused considerable damage to the tumour cells, has been observed by Crabtree. This is in agreement with the results obtained here with X-rays. The aerobic glycolysis seems to

be quite resistant to the action of X-rays or radium (see Crabtree) and is affected only after the radiation has caused considerable degeneration of the tumour tissue. On the other hand Adler [1930] found a gradual increase in the aerobic glycolysis with small amounts of X-rays. The decrease in the oxygen uptake observed also by Cramer after continued irradiation with radium is possibly a secondary effect. However, the decrease in the R.Q. which usually occurs when there is any effect upon growth seems likely to be an immediate effect of radiation and indicates a definite alteration in the chemical activity of the cell. This alteration in the metabolism may be important as a clue to the mechanism of the action of radiation upon cell metabolism.

#### SUMMARY.

1. When two tumours are implanted in one animal their growth rates and metabolisms usually correspond closely. It has been found practicable to irradiate one of such duplicate tumours and to observe the effects of X-radiation on the growth, histology and metabolism of the treated tumour, using the untreated tumour as a control.

2. The sequence of histological effects of X-rays seems to be a reduction in the number of mitoses or a formation of enlarged cells, a gradual degeneration of tumour cells and finally an infiltration of connective tissue which smothers the remaining cells.

3. The aerobic glycolysis continues unimpaired during treatment with X-rays until after a very considerable amount of degeneration of tissue has occurred.

4. There is a lowering of the oxygen uptake, which may be a secondary effect of damage done to the tissues by radiation.

5. With the Philadelphia 1 sarcoma, X-ray treatment always lowers the R.Q. Since this occurs whenever the growth has been affected in the least, it is possibly a primary effect of X-rays upon the metabolism.

6. The Philadelphia 1 sarcoma is much less sensitive to the action of X-rays than the Walker 256 carcinoma. There are indications that 24-hour starvation or injection of insulin increases this sensitivity although such an increase in sensitivity does not appear to be directly associated with a lowered blood sugar level.

The authors are indebted to Dr K. A. C. Elliott for his advice and help on the manometric studies and to Dr Ellice McDonald, Director, for his constant support throughout this work.

# CCLXXXVIII. INHIBITORY ACTION OF THE LOWER ALIPHATIC ACIDS AND ALDEHYDES ON CYTOCHROME REDUCTION IN YEAST.

By LYLE VIBERT BECK.

*From the Cancer Research Laboratory, Graduate School of Medicine, University of Pennsylvania, Philadelphia, Pa., and Lilly Research Laboratories, Marine Biological Laboratory, Woods Hole, Massachusetts.*

*(Received August 12th, 1935.)*

KEILIN [1929; 1933] has demonstrated the important rôle which cytochrome plays in cellular respiration as carrier between activated oxygen and activated substances. He has opened up the possibility of making use of the rate of cytochrome reduction as a measure of intracellular dehydrogenase activities, in much the same way in which methylene blue has been used by Thunberg and his associates [1930; Ahlgren, 1925]. Keilin has further shown that the state of oxido-reduction of cytochrome is of value in deciding which part, if any, of the indophenol oxidase-cytochrome-dehydrogenase respiratory mechanism is affected by various respiratory inhibitors. For example cyanide, hydrogen sulphide and carbon monoxide inhibit respiration by blocking the indophenol oxidase system whilst the narcotics act by blocking the dehydrogenases.

Beck and Robin [1934] have found that Fleischmann's yeast suspended in acetate buffers requires a much longer time to reduce cytochrome and oxidation-reduction indicators than does yeast suspended in citrate-phosphate and phosphate buffers covering the same  $p_H$  range (4.0-7.0). In parallel experiments on yeast vitally stained with methyl red the acetate buffers were found to induce rapid intracellular acidification whilst the other buffers had no such effect. The inhibitory effects of the acetate buffers were therefore attributed to intracellular acidification acting on dehydrogenase systems.

These findings were of sufficient interest to suggest further experimentation, to determine, if possible, whether the action of the acetate buffers might be due to factors other than increase in intracellular acidity. Experiments were therefore performed in which the first six aliphatic acids were compared with one another and with hydrochloric and citric acids, the last two agents having been selected because of their slow penetration into cells. The acids were also compared with some of the chemically homologous aldehydes, alcohols and urethanes, as to their action on cytochrome reduction. The actions of acetic and butyric acids, each in the presence and absence of its sodium salt, have been determined with particular care, because of the possible bearing of the data on the problem of penetration into cells of the salts of penetrating acids.

## EXPERIMENTAL.

### *Materials.*

Fleischmann's yeast<sup>1</sup> was employed, since Keilin has found that commercial yeast constitutes very excellent material for the study of cytochrome oxidation and reduction, and since yeast cells are not injured by external  $p_H$  values so low (2.0-5.0) as to be toxic to most cells [Richards, 1932].

<sup>1</sup> Fleischmann's yeast contains more than one strain of yeast and many bacilli and cocci, as well as starch. The author feels that its use is justified in experiments of the kind reported in this paper, since consistent results were always obtained.

*Methods.*

A 10 % by weight suspension of Fleischmann's yeast in tap-water was aerated vigorously for 20-30 min. and then kept for 2 hours. Samples for testing the rate of cytochrome reduction were prepared in amounts of 4-5 ml. of yeast suspension in each of a series of test-tubes. To determine a normal or basic rate of cytochrome reduction 0.5 ml. of tap-water was added to the yeast suspension in one of the test-tubes. Its contents were shaken together and poured into a small test-tube placed between a good source of light and a hand spectroscope. The suspension was then aerated in the small test-tube at a constant pressure for exactly 1 min., and the time required to secure reappearance of the D band of reduced cytochrome determined with a stop-watch. The value so obtained is termed the "2-min." value, since approximately 2 min. are required for manipulation and aeration. Two hours later this same suspension was tested again, in exactly the same manner, giving another value, called the "2-hour" value. By this method, the basic reduction time values for different samples were found to agree satisfactorily with one another, as may be seen from the tables.

The same procedure was employed to test the reaction of the yeast to a given chemical solution, except that 0.5 ml. of a solution of the chemical in ten times the desired concentration was substituted for the 0.5 ml. of tap-water.

*Effects of aliphatic acids and aldehydes on rate of cytochrome reduction.*

The effects on cytochrome reduction of the six lowest fatty acids, HCl and citric acid, in 0.01 and 0.001 *M* concentration, are shown in Table I. The comparative effects on cytochrome reduction of the acids, formic to butyric, and their corresponding aldehydes, again in 0.01 and 0.001 *M* concentration, are shown in Tables II and III.

Table I. *Cytochrome reduction in yeast as affected by various acids.*

Agent to which yeast sample was exposed	Seconds required to secure return of D band of reduced cytochrome					
	Values for yeast exposed to acids in 0.01 <i>M</i> conc.			Values for yeast exposed to acids in 0.001 <i>M</i> conc.		
	Values after 2-min. exposure	Values after 2-hour exposure	Values after washing and addition of glucose	Values after 2-min. exposure	Values after 2-hour exposure	
Controls (tap-water)	19, 19	18, 21	11, --	19, 24	28, 28	
Hydrochloric acid	22	34	8	29	32	
Citric acid	24	30	10	30	34	
Formic acid	(0)*	(0)†	9, 10	30	28	
Acetic acid	38	45	10	27	26	
Propionic acid	73	77	9	28	31

Valeric acid	123	142	9	29	36	
Hexanoic acid	123	154	14	28	38	
Citrate-PO <sub>4</sub> buffer, pH 4.0	17	24	10	24	31	

\* Formic acid, in 0.01 *M* concentration, differs markedly from the other fatty acids in its action on cytochrome, which it brings into a condition where weak bands of the reduced form are seen; a condition not affected by long and vigorous aeration or long periods of standing without aeration.

† The citrate-phosphate buffer was used in 1/10 the standard concentration.

Table II. *Comparison of aldehydes with fatty acids in their effects on cytochrome reduction.*

Agent to which yeast sample was exposed	Seconds required to secure return of D band of reduced cytochrome				
	Values* for yeast exposed to agents in 0.01 <i>M</i> conc.			Values* for yeast exposed to agents in 0.001 <i>M</i> conc.	
	Values after 2-min. exposure	Values after 2-hour exposure	Values after washing and addition of glucose	Values after 2-min. exposure	Values after 2-hour exposure
(Controls (tap-water)	47	47	33	63	66
Formaldehyde	65	(0)†	32	—	—
Acetaldehyde	61	59	35	—	—
Acetic acid	74	108	33	—	—
Propaldehyde	67	64	31	—	—
Propionic acid	127	131	32	—	—
Butyraldehyde	97	108	34	68	71
Butyric acid	140	159	34	77	73
Valeraldehyde	—‡	—‡	—	76	69
Valeric acid	—‡	—‡	—	83	73

\* Each value, as given, is the average to the nearest whole number of seconds of three separate determinations.

† Like formic acid, formaldehyde in 0.01 *M* concentration brings cytochrome into a condition where weak bands of the reduced form are seen, a condition not affected by long and vigorous aeration or long periods of standing without aeration.

‡ Valeraldehyde is not sufficiently soluble to permit the preparation of a 0.1 *M* stock solution, as required by the technique employed with all the other agents, hence no attempt was made to compare valeraldehyde with valeric acid and with the lower acids and aldehydes at 0.01 *M* concentration.

Table III. *Statement of results with aldehydes and acids, in 0.01 *M* concentration, in terms of relative velocities.*

Agents		Aldehydes		Acids	
		Velocity* of cytochrome reduction	% inhibition of cytochrome reduction	Velocity* of cytochrome reduction	% inhibition of cytochrome reduction
Controls	2-min. values	21.3	—	21.3	—
	2-hour values	21.3	—	21.3	—
2-carbon compounds	2-min. values	16.4	23	13.5	37
	2-hour values	16.9	21	9.3	56
3-carbon compounds	2-min. values	14.9	30	7.9	63
	2-hour values	15.7	26	7.6	64
4-carbon compounds	2-min. values	10.3	52	7.15	66
	2-hour values	9.3	56	6.3	70

\* Velocity of cytochrome reduction is defined as  $1000/t$ , where  $t$  = no. of seconds required to secure return of the D band of reduced cytochrome (see Table II).

The effects of these various agents in 0.01 *M* concentration may be summarised as follows.

(a) Formic acid and formaldehyde differ from all the other agents in bringing cytochrome into a peculiar condition characterised by the appearance of weak bands of the reduced form. This condition is not affected by vigorous and long-continued aeration or by long keeping without aeration. Formic acid acts more quickly than does formaldehyde in bringing cytochrome into this condition.

(b) The remaining aliphatic acids and aldehydes strongly inhibit cytochrome reduction, each of the acids being considerably more effective than the corresponding aldehyde.

(c) The greater the length of the aliphatic chain of an acid or aldehyde the greater is its effectiveness in inhibiting cytochrome reduction.

(d) The aliphatic acids are far more effective than are the stronger but much more slowly penetrating hydrochloric and citric acids.

(e) The effects of all these agents on cytochrome reduction may be completely reversed by thorough washing and addition of the substrate glucose.

These various agents have relatively little effect on cytochrome reduction when used in 0.001*M* concentration.

*Effects of aliphatic alcohols and urethanes on rate of cytochrome reduction.*

The alcohols methyl to amyl and the urethanes ethyl, propyl and butyl were tested in 0.01*M* concentration. At this concentration, the urethanes were found not to affect cytochrome reduction, whilst of the alcohols only methyl and ethyl had any effect, and their effects were acceleration rather than retardation of cytochrome reduction.

*Relative penetrations of the various acids into yeast cells.*

Since the relatively weak aliphatic acids were far more effective in inhibiting cytochrome reduction than were hydrochloric and citric acids, it was thought of interest to compare these various acids, at least qualitatively, as to rate and degree of penetration into the yeast. This was done by a study of colour changes in yeast vitally stained with propyl red<sup>1</sup> and then treated with the various acids.

The tests were carried out by adding propyl red in 0.002 % concentration to phosphate buffer of  $p_H$  5.4. After 3 min., samples of the stained yeast were centrifuged, washed once with fresh citrate-phosphate buffer of  $p_H$  5.4 to remove as completely as possible the propyl red which had failed to penetrate into the cells and treated with one of the acids in 0.01, 0.0033 or 0.001*M* concentration. The colour changes in each sample during the next 10 min. were noted with the naked eye by comparison with a control sample of stained yeast.

With the exception of formic, all the fatty acids and in all the concentrations employed induced a very rapid change in colour of the stained yeast; this method was unsatisfactory for detecting differences in rate of penetration within the series. Formic acid induced a pronounced change in colour when used in 0.01*M* concentration and a faint colour change when used in 0.0033*M* concentration. Hydrochloric and citric acids in 0.01*M* concentration induced a slow faint change of colour of the stained yeast, an effect quite possibly due to colour changes of dye outside the yeast. In the two lower concentrations neither agent produced any colour changes in the yeast suspensions. The order of penetration of these acids into Fleischmann's yeast, is, by this method: valeric to acetic, formic, citric, hydrochloric.

<sup>1</sup> Like methyl red [Chambers, 1930], propyl red stains cells only from acid media. Propyl red is more satisfactory than methyl red for studying acid penetration into yeast cells, since it gives a deeper stain, and the fading of its colour is slower. This fading of methyl red and propyl red in the presence of yeast has not been observed with other cells, such as marine eggs and amoebae. It seems likely that it is the result of an irreversible reduction of these compounds. The effect is not reversible with oxidising agents, e.g. ferrioyanide.

*Counteracting effects of Na acetate and Na butyrate on the inhibition of cytochrome reduction by acetic acid and butyric acid respectively.*

In so far as the salts of the fatty acids penetrate they may be expected to buffer the intracellular reaction back towards its original condition and so may be expected to counteract in some degree any part of the action of the acids on cytochrome reduction due to intracellular acidification.

Yeast treated with 0.01M acetic acid was compared with yeast treated with 0.01M acetic acid + 0.03M sodium acetate and with yeast treated with 0.01M acetic acid + 0.09 M sodium acetate as to rate of cytochrome reduction. The principle of keeping the concentration of the acid constant while varying that of the salt is adopted from Lillie [1926] and Howard [1932]. These experiments show that as a rule the acid alone inhibits cytochrome reduction to a greater degree than the acid *plus* its sodium salt. This differential effect can be detected within 2 min. after beginning treatment of the yeast with the acid or acid-salt solution. In part A of Table IV are summarised the results of a lengthy experiment carried out to secure sufficient data on this difference for the application of statistical methods. The results of this experiment demonstrate that the observed counteracting effects of sodium acetate are not due to chance.

An experiment carried out in exactly the same manner with 0.01M butyric acid, and 0.01M butyric acid + sodium butyrate gave the data shown in summary form in part B of Table IV, from which it is evident that sodium butyrate is considerably more effective in counteracting butyric acid than is sodium acetate in counteracting acetic acid.

Table IV.

Part A—*Comparison of (a) 0.01 M acetic acid, (b) 0.01 M acetic acid + 0.09 M Na acetate in their effects on cytochrome reduction.*

Part B—*Comparison of (a) 0.01 M butyric acid, (b) 0.01 M butyric acid + 0.09 M Na butyrate in their effects on cytochrome reduction.*

Agent to which yeast samples were exposed	Seconds required to secure return of D band of reduced cytochrome (each value for (a) and (b) is the average of 10 determinations $\pm$ its standard error)	
	Values for 2 min. exposure period	Values for 2-hour exposure period
<b>Part A</b>		
Controls (tap-water)	19.3, 22.0	29.1, 29.4
0.01 M acetic acid (a)	43.37 $\pm$ 0.80	48.07 $\pm$ 0.37
0.01 M acetic acid + 0.09 M Na acetate (b)	40.14 $\pm$ 0.73	40.13 $\pm$ 0.32
Differences and standard errors of differences between (a) and (b)	3.23 $\pm$ 1.27	7.94 $\pm$ 0.49
<b>Part B</b>		
Controls (tap-water)	34.7, 36.8, 34.1	38.0, 40.3, 33.4
0.01 M butyric acid (a)	90.05 $\pm$ 1.59	94.10 $\pm$ 1.65
0.01 M butyric acid + 0.09 M Na butyrate (b)	66.33 $\pm$ 0.89	64.07 $\pm$ 0.91
Differences and standard errors of differences between (a) and (b)	23.72 $\pm$ 1.83	30.03 $\pm$ 1.88

These results do not establish the mode of action of sodium acetate and sodium butyrate in counteracting the corresponding acids. The action of the salts might be due, in part or in whole, to any of the following: (I) the considerably greater osmotic pressures of the solutions containing both the acid and the salt, (II) the considerable difference in external  $p_H$  in the two cases ( $p_H$  3+ for

0.01 *M* acetic acid or butyric acid;  $p_H$  6— for 0.01 *M* acetic or butyric acid *plus* the corresponding salt in 0.09 *M* concentration), (III) utilisation of sodium acetate or sodium butyrate as substrate for cytochrome reduction, (IV) penetration of the salt to a degree sufficient to overcome in some degree the intracellular acidification induced by the acid. Experiments were therefore performed to determine to what extent (I), (II) and (III) may account for the observed counteracting effects of the fatty acid salts.

(I) *The considerably greater osmotic pressures of solutions containing both acid and salt.* Yeast was treated with (a) 0.01 *M* acetic acid, (b) 0.01 *M* acetic acid *plus* 0.09 *M* sodium chloride, (c) 0.01 *M* acetic acid *plus* 0.09 *M* sodium acetate. The results of these experiments were that reduction times for yeast treated with (a) and (b) were identical, within the limits of error of the method, whilst those for yeast treated with (c) were consistently smaller than those for yeast treated with (a) or (b). These experiments therefore rule out the difference in osmotic pressure in the two cases as the responsible factor.

(II) *The considerable difference in external  $p_H$  in the two cases.* Two experiments were performed to test the effects of variation in external  $p_H$  on cytochrome reduction. In the first of these experiments the yeast was exposed to citrate-phosphate buffers of  $p_H$  3.0, 4.0, 5.0 and 6.0 in 1/10 the standard concentrations. In the second experiment the inhibiting agent ethylurethane was added in concentration of 3% to each of the buffer solutions. The data secured in these two experiments are shown in Table V which show that for a treatment period

\* The citrate-phosphate buffers were employed in 1/10 the standard concentration.

of approximately 2 min., variation in the  $p_H$  of the external medium over the range 3.0–6.0 has no effect on cytochrome reduction; for a treatment period of 2–3 hours there is definite inhibition of cytochrome reduction in the yeast treated with the buffers of  $p_H$  3.0 and 4.0. This action is quite possibly due in part at least to slow penetration of citric acid into the yeast; the magnitude of the difference is not nearly so great as that between butyric acid and butyric acid *plus* its salt, but is quite comparable with the difference in action of acetic acid and acetic acid *plus* its salt.

(III) *Utilisation of sodium acetate and sodium butyrate as substrates for cytochrome reduction.* Experiments on (a) untreated yeast and (b) yeast treated with 0.09 *M* sodium acetate or sodium butyrate gave the results shown in Table VI, from which it is evident that, under the experimental conditions employed

Table VI.

Part A—Cytochrome reduction in (a) untreated yeast, (b) yeast exposed to 0.09 M sodium acetate.

Part B—Cytochrome reduction in (a) untreated yeast, (b) yeast exposed to 0.09 M sodium butyrate.

Seconds required to secure return of D band of reduced cytochrome (each value for (a) and (b) is the average of 8 determinations  $\pm$  its standard error)

Agent to which yeast samples were exposed	Values for 2-min. exposure period	Values for 2-hour exposure period
Part A		
(a) Tap-water	41.7 $\pm$ 1.11	44.6 $\pm$ 1.14
(b) 0.09 M Na acetate	38.4 $\pm$ 1.17	41.8 $\pm$ 1.30
Differences and standard errors of differences between (a) and (b)	3.3 $\pm$ 1.61	2.8 $\pm$ 1.73
Part B		
(a) Tap-water	42.1 $\pm$ 0.63	37.3 $\pm$ 0.32
(b) 0.09 M Na butyrate	40.3 $\pm$ 0.49	36.4 $\pm$ 0.47
Differences and standard errors of differences between (a) and (b)	1.8 $\pm$ 0.8	0.9 $\pm$ 0.57

in the acid-salt experiments, it is very unlikely that sodium butyrate acted to any appreciable degree as substrate for cytochrome reduction, and certainly not to an extent sufficient to account for any substantial part of the sodium butyrate-counteracting effect. On the other hand, the findings with sodium acetate suggest possible utilisation of this substance for cytochrome reduction to an extent sufficient to account for at least part of the sodium acetate-counteracting effect.

It should be noted in passing that utilisation of a compound as substrate for cytochrome reduction should not be interpreted as indicating non-penetration of the compound, but rather the reverse. The reducing mechanisms of the cell are in the main intracellular, as shown by the inability of starfish eggs to reduce non-penetrating oxidation-reduction indicators unless these are micro-injected [Chambers *et al.*, 1929; 1931] and the inability of yeast to reduce non-penetrating indicators [Beck and Robin, 1934].

#### DISCUSSION.

The comparative ineffectiveness of hydrochloric and citric acids is to be attributed to their poor powers of penetration into the cells, it being generally known that strongly dissociated acids penetrate cells much less readily than do weakly dissociated, lipid-soluble acids, *e.g.* the fatty acids. This relation was confirmed for the yeast cell by a study of colour changes in yeast vitally stained with propyl red and then treated with the various acids.

The experimental findings indicate that formic acid and formaldehyde act on the cytochrome reduction process in a manner quite different from that of any of the other agents employed or any of those employed by Keilin. In the presence of 0.01 M formic acid cytochrome is immediately, and in the presence of 0.01 M formaldehyde eventually, brought into a peculiar condition, in which weak bands of the reduced form are present, and in which the cytochrome is resistant both to oxidation and reduction. Tentatively these results may be interpreted to indicate (a) reaction of formic acid and of formaldehyde with cytochrome, the formic acid-cytochrome and the formaldehyde-cytochrome complexes both being far

more resistant to changes in state of oxidation-reduction than is cytochrome itself, or (b) marked inhibition of both oxidase and dehydrogenase systems by formic acid and formaldehyde.

A comparison of the effects on cytochrome reduction exercised by the remaining fatty acids and by the corresponding aldehydes, alcohols and urethanes indicates that the carbonyl group in combination with an aliphatic chain is partly responsible for the inhibitory action exercised by the acids and entirely responsible for that exercised by the aldehydes. An aliphatic chain in combination with an alcohol or carbamate group is completely ineffective when such compounds are used in 0.01 *M* concentration. The manner in which the effectiveness of the acids and aldehydes increases with increase in length of the aliphatic chain is entirely analogous to that found by Warburg [1928] for the action of urethanes on respiration, and the same type of mechanism may be postulated, *i.e.* blocking of (dehydrogenase) centres concerned in cytochrome reduction by specific adsorption of the acids and aldehydes at these centres. As with the urethanes, the adsorption would be considered as increasing with increase in length of the aliphatic chain. The carbonyl group would be considered as a key group whose presence in the molecule is required if it is to be adsorbed, and it should be present in compounds used as substrates, as well as those which exercise an inhibiting effect.

The greater effectiveness of the fatty acids as compared with the corresponding aldehydes is the only part of the action of the acids attributable to the increase in intracellular acidity which they induce. However, this part of the total acid inhibition is considerable (see Tables II and III).

The counteraction of butyric acid by sodium butyrate and of acetic acid by sodium acetate constitutes additional evidence that part of the inhibitory effects of fatty acids on cytochrome reduction is due to the intracellular acidification which they induce. The counteracting effect of sodium butyrate can certainly not be attributed to differences in osmotic pressure or external  $p_H$  or to its utilisation as substrate for cytochrome reduction. The most plausible interpretation of this rapid counteracting effect appears to be that sodium butyrate and sodium acetate penetrate yeast cells in the presence of the corresponding acid at a rate and to an extent sufficient to overcome in some degree that portion of the inhibitory effects of the acid due to intracellular acidification. This interpretation is in accord with the relatively high penetrating power attributed to the sodium salts of rapidly penetrating acids by Smith and Clowes [1924], Lillie [1926] and Howard [1932]. For discussion and literature of the salt penetration problem the reader is referred to Howard.

#### SUMMARY.

1. A method is described for bringing a 10 % suspension of Fleischmann's yeast into such condition that different control samples give values for rate of cytochrome reduction which agree with one another satisfactorily.

2. When used in 0.01 *M* concentration the various agents employed were found to have the following effects on the behaviour of cytochrome.

- (a) Formic acid and formaldehyde bring cytochrome into a condition where weak bands of reduced cytochrome are maintained, whether the yeast be vigorously aerated or kept for a long time without aeration.

- (b) Cytochrome reduction is markedly inhibited, within 2 min. and in a completely reversible manner, by the weak but rapidly penetrating aliphatic acids, acetic to hexanoic.

(c) Acetaldehyde, propaldehyde and butyraldehyde also inhibit cytochrome reduction, each to a less degree than the corresponding acid.

(d) The greater the length of its aliphatic chain the more effective is an acid or aldehyde in inhibiting cytochrome reduction.

(e) The very rapidly penetrating alcohols methyl to amyl and the urethanes ethyl, propyl and butyl do not inhibit cytochrome reduction when used in this concentration (0.01 *M*).

(f) The strong but slowly penetrating acids, citric and hydrochloric, inhibit cytochrome reduction more slowly and much less than do the aliphatic acids.

(g) The effects of all of these agents may be completely reversed by washing and addition of the substrate glucose.

3. Employing the same methods, sodium acetate and sodium butyrate were found rapidly to counteract in part the inhibitory action of the corresponding acids on cytochrome reduction.

# CCLXXXIX. THE RESPIRATORY QUOTIENTS OF NORMAL AND TUMOUR TISSUE.

By KENNETH ALLAN CALDWELL ELLIOTT AND ZELMA BAKER.

*From the Cancer Research Laboratories, Graduate School of Medicine,  
University of Pennsylvania, Philadelphia, Pa.*

*(Received July 6th, 1935.)*

THE respiratory quotients of slices of various tissues have been studied by manometric methods by a number of workers, and especially by Dickens and Simer [1930; 1931]. In the course of work on other problems many of the results of the authors named have been confirmed, but in some cases important differences from their findings have been observed. A large number of experiments have therefore been made to confirm these agreements and differences and the results are reported in the present paper.

## EXPERIMENTAL.

The differential manometric apparatus of Dixon and Keilin [1933] was used and the technique described by Elliott and Schroeder [1934] followed. Except where otherwise stated, the bicarbonate-containing medium used was that described by Krebs [1932] and it contained 0.24% glucose. The experimental period was 90 min. unless otherwise specified. The R.Q. is given by the expression

$$\frac{(h_1 - h_2) \cdot k_{\text{CO}_2}}{h_2 \cdot k_{\text{O}_2}},$$

where  $h_1$  is the reading obtained when acid has been tipped into both vessels, killing the tissue and liberating total  $\text{CO}_2$ , and  $h_2$  is the reading given after all  $\text{CO}_2$  has been absorbed by alkali, being a direct measure of the  $\text{O}_2$  uptake. (In a normal experiment both  $h_1$  and  $h_2$  are negative.)  $k_{\text{O}_2}$  and  $k_{\text{CO}_2}$  are the vessel constants for oxygen and carbon dioxide. Small errors in  $h_2$  have a negligible effect on the observed R.Q., but errors in  $h_1$  can affect the value appreciably, especially when the oxygen uptake is not very large. For this reason a large number of blank experiments were made, *i.e.* experiments for the usual period but without tissue. It was found in the majority of cases that there was a negative  $h_1$  reading, usually small but occasionally quite large, up to 2 mm., equivalent to 25  $\mu\text{l.}$  of gas. When the total oxygen uptake is 500  $\mu\text{l.}$ , such an error would affect the R.Q. by about 0.05. In 33 blank experiments with various manometers, the  $h_1$  reading varied from 0.0 to -2.0 mm., the mean being -0.9 mm., corresponding to 12  $\mu\text{l.}$  of gas. All our R.Q. values have been corrected for this mean error, and the limits of error are shown in the tables. (The actual uncorrected value obtained for the R.Q. is in each case the lower limit of the value given in the tables.) It is not understood why this error in  $h_1$  should occur, or why it is always negative. Experiments in which anhydrous lanoline was placed on the bottom of the vessel showed that this grease absorbed a large amount of  $\text{CO}_2$ , or it occluded bicarbonate, and the  $\text{CO}_2$  was only slowly liberated by acid. Rubber grease (Lubriscal, A. H. Thomas Co.) did not do this and does not melt at 37° as lanoline does. The use of rubber grease throughout appeared to give slightly better results, though often an appreciable negative  $h_1$  reading was still observed.

*Terms.*

We have employed the term,  $-Q_{O_2}$ , introduced by Warburg to express the rate of oxygen uptake, and the term,  $Q_A$ , as used by Elliott and Schroeder [1934] to express the rate of acid formation or glycolysis.  $Q_A^{N_2}$  and  $Q_A^{O_2}$  differentiate acid formations under aerobic and anaerobic conditions.

*Chick embryo, brain, retina.*

With these three tissues, Dickens and Šimer found R.Q. 1. For the chick embryo, Needham [1933] also found R.Q. 1, and we have confirmed this result. Thus, in two experiments with 4-day chick embryos the results shown in Table I were obtained.

Table I. *Four-day chick embryos.*

	Dry wt. mg.	$-Q_{O_2}$	R.Q.	$Q_A$
9 large embryos in each vessel	28.9	13.3	$0.99 \pm 0.02$	+ 0.6
11 smaller embryos in each vessel	17.0	13.2	$1.05 \pm 0.04$	- 1.3

With brain cortex of rats and rabbits, we have not observed an R.Q. as high as 1.0 except in one abnormal experiment described below. Table II shows a number of the results. As far as possible, pure cortical matter was used and the slices were handled as gently as possible. In the last experiment on rabbit tissue, which was regarded at the time as the best experiment, a relatively large amount of tissue was used, and the slices, before introduction into the vessels, were drained, not on filter-paper, but on thin glazed perforated porcelain discs with filter-paper underneath the discs.

Mean 0.88

Ashford and Holmes [1931] obtained results similar to those in Table II with rabbit brain in ordinary Ringer solution using the rather crude method described by Dixon and Elliott [1929]. With rat brain Himwich *et al.* [1934] found the R.Q. to be 0.92 using the method of Warburg with phosphate-containing medium.

Dickens and Šimer [1931] mention that older rats tend to have a lower brain R.Q.; all animals here used were young and healthy. The Krebs medium generally used in this work contains traces of Mg,  $\text{PO}_4$  and  $\text{SO}_4$  as well as the other salts present in the bicarbonate medium of Warburg [1926] which was used by Dickens and Šimer in their later work [1931]. Several duplicate experiments with the two media showed that differences in medium could not account for the different results. It is interesting to note however that the aerobic glycolysis or acid formation,  $Q_A$ , is in every case higher in the less complete medium of Warburg.

A possible explanation of the results of Dickens and Šimer lies in the fact that their experimental period was 5 hours. This is suggested by Exp. 10, Table II. For this experiment, slices were obtained from four rat brains and fair samples taken for each of three manometers. One of these manometers was run for the usual 90 min., using a large amount of tissue to minimise the relative effect of experimental errors. The second manometer ran for 5 hours and it is seen that the average R.Q. is definitely higher over the longer period. The tissue for the third manometer was kept for 3 hours at  $37^\circ$  in Krebs medium with  $\text{O}_2/\text{CO}_2$  gas mixture bubbling through the medium. The tissue, after having been rinsed in bicarbonate-free Ringer solution in the usual way, was then introduced into the vessels of the manometer, and a 2-hour run was made. In this case the R.Q. was unity. A further interesting observation was made in this experiment. With the short period manometer the glycolysis was small and the movement of the manometer fluid during the experimental period was very small. In the 5-hour experiment the manometer fluid scarcely moved for the first 3 hours and then started a movement in the positive direction, indicating the onset of glycolysis. With the third manometer, the tissue for which had already been incubated aerobically for 3 hours before introduction, the manometer fluid started moving at once and the glycolysis was quite considerable. It appears therefore that when the tissue is kept for some time, abnormal metabolism sets in with higher R.Q. and aerobic glycolysis. Rosenthal [1931] observed an increased anaerobic glycolysis after a preliminary period of aerobiosis. Experiments with rat brain in the absence of glucose showed that the oxygen uptake was much decreased and the R.Q. was variable but not necessarily lowered. These results agree with those of Loebel [1925] and of Dickens and Greville [1933, 1]. Exp. 14 illustrates the well-known high anaerobic glycolysis of brain tissue [Warburg *et al.*, 1924; Loebel, 1925].

For the experiments with retina, the room was darkened and the retinas extracted under the least possible light. For two experiments (Nos. 4 and 6) the manometer vessels were painted black with a suspension of lamp-black in shellac. After removing the eyes from the animals they were cut equatorially by one snip with fine scissors, the lens was removed and the retina carefully dislodged with a thin flattened glass spatula and dropped into Krebs medium through which  $\text{O}_2/\text{CO}_2$  was passing. Immediately before the experiment, the tissue was rinsed in ordinary Ringer solution, drained on thin glazed perforated discs, and equal amounts, as judged by eye, were introduced into the two vessels. In Table III, results of the experiments are shown and again it is seen that R.Q. values of less than unity were obtained. The discrepancy between these

results and those of Dickens and Šimer may be explained, as with brain, by the longer experimental period used by the latter authors. A very high aerobic glycolysis was found, as was first observed by Warburg *et al.* [1924]. In Exp. 3, where both Krebs and Warburg media were used, the R.Q. were not significantly different, nor were the oxygen uptakes, considering the high probability of error in determining such small dry weights. The glycolysis in the simpler medium however was considerably higher than in the more complete medium of Krebs. Warburg *et al.* [1924] and Kubowitz [1929] consider that the aerobic glycolysis found with retina is not normal but is produced by damage; in this case it would seem that use of the Krebs medium results in less of this damage. The same would apply to the effects mentioned above with brain tissue. In the first three experiments of Table III, the movement of the manometer fluid followed an

Table III. *Rat retinas.*

	Approx. no. of retinas in each vessel	Dry wt. mg.	$-Q_{O_2}$	R.Q.	$Q_A$	Remarks
1	5	4.7	26.4	$(0.70 \pm 0.05)$	49.5	2 hours; $O_2$ uptake too small for reliable R.Q.
2	8	6.6	23.3	$0.89 \pm 0.03$	37.0	Krebs medium
3	8	4.7	26.7	$0.93 \pm 0.04$	49.8	Warburg medium
4	10	6.1	32.6	$0.92 \pm 0.03$	43.8	2 hours
5	11	8.0	26.7	$0.91 \pm 0.03$	29.7	2 hours
6	20	13.6	27.9	$0.96 \pm 0.02$	22.1	2 hours
6	25	18.6	27.5	$0.87 \pm 0.02$	20.7	1½ hours
Mean			0.91			

almost linear course showing that the rate of glycolysis was almost constant. In Exp. 4 the glycolysis fell off somewhat and in Exps. 5 and 6, where larger amounts of tissue were used, the rate of glycolysis fell off continuously and considerably; in the last 30 min. with Exp. 4 the manometer moved only about  $\frac{1}{4}$  as much as in the first 30 min. This falling off is reflected in the lower average acid formation ( $Q_A$ ) with Exps. 4 and 5. This change in the rate of glycolysis can scarcely be explained by a decrease in the concentration of glucose since in all experiments 7.2 mg. glucose were present initially and the total glucose that would be removed by glycolysis varied between 2.1 mg. for Exp. 1 and 2.7 mg. for Exps. 4 and 5. A further 0.4–1.2 mg. might have been removed if only carbohydrate or lactate were oxidised, but the low R.Q. does not indicate this. The glycolysis therefore falls off much more rapidly than the glucose concentration. Further, the bicarbonate concentration in the medium was more than sufficient to maintain a normal  $p_H$ . Possibly there is some glycolysis-inhibiting substance in the retina which becomes effective when there is a greater amount of retina in the 3 ml. of medium.

#### *Testis.*

For this tissue Dickens and Šimer [1931] found R.Q. about 0.9 and results shown in Table IV are similar or a little higher. In the absence of glucose the respiration is decreased and the R.Q. lowered, and similar results are given by Dickens and Greville [1933, 1]. The high anaerobic glycolysis [Warburg, 1927] is shown in one experiment.

#### *Liver.*

Dickens and Šimer [1931] found that the R.Q. of liver tissue in bicarbonate-Ringer solution varied between 0.55 and 0.76, the lower values being obtained with fasting animals, and recently Gemmill and Holmes [1935] gave values

Table IV. *Testis.*

Dry wt. mg.	$-Q_{O_2}$	R.Q.	$Q_A$	Remarks
14	12.4	$0.91 \pm 0.05$	4.8	—
31	11.8	$0.96 \pm 0.02$	4.3	—
18	11.1	0.92	6.0	1 hour. $O_2$ uptake too small for accuracy
27	11.9	$0.95 \pm 0.03$	4.9	—
13	6.5	$0.69 \pm 0.09$	2.1	Glucose absent
33	4.7	$0.69 \pm 0.05$	1.1	Glucose absent
33	6.6	$0.57 \pm 0.04$	1.7	Glucose absent
17	—	—	13.4	Glucose present, anaerobic

between 0.61 and 0.87 for rats on a normal diet. Results obtained in this laboratory with well-fed animals are in general higher than these figures and very frequently R.Q. values of 1 have been obtained. Out of 78 experiments with rats on the normal diet, or especially well-fed, 42 gave R.Q. values between 0.95 and 1.15 and the remainder varied between 0.95 and 0.70. The animals used were all of the Germantown albino strain between 3 and 12 months old, and they were fed on a standard diet of lettuce, bread, boiled mixed cereal grains and some milk. It may be mentioned that at first it appeared that a very high R.Q. was associated with cancer in other parts of the body, with pregnancy and with the healing of wounds, since a long series of R.Q. values of unity were obtained with the livers of rats in such conditions. This now seems to have been simply coincidence, and no consistent differences between normal and tumour-bearing animals in the  $Q_{O_2}$ , R.Q. or  $Q_A$  of their livers were found. Such high R.Q. values could not be regularly and deliberately induced by special feeding. The difference between these results and those of the above authors makes it seem possible that the metabolism of rat liver tissue may depend to some extent on the strain to which the animal belongs, although Dr M. Dixon (private communication), working in the same laboratory as Gemmill and Holmes, has found liver R.Q. values of 1. The R.Q. was not affected by using the Warburg bicarbonate medium in place of the usual Krebs medium.

The anaerobic glycolysis of a number of livers was measured. In the case of livers with high R.Q. the anaerobic glycolysis was rapid, as high as that of testis or brain, but usually it fell off very quickly. This falling off may be associated with the disintegration of the tissues under anaerobic conditions. It should be emphasised that the glycolysis of liver tissue takes place at the expense of its glycogen stores [Rosenthal and Lasnitzki, 1928; Rosenthal, 1929]. The rate of glycolysis is usually even higher when glucose is absent from the medium than when it is present. Similarly the R.Q. is independent of the presence of glucose in the medium [see also Dickens and Greville, 1933, 1]. In fasting rats both the R.Q. and the glycolysis are low and the livers contain practically no glycogen. With fasting rats the R.Q. values observed by us are lower than those of Dickens and Šimer. In 11 experiments with livers of normally fed mice one value of 0.99 and one of 0.93 were found, the remainder being between 0.49 and 0.81. A few of the numerous results obtained are shown in Table V.

#### *Kidney.*

For rat kidney (cortex *plus* medulla) Dickens and Šimer [1930; 1931] gave R.Q. values from 0.76 to 0.92, and the results given in Table VI for cortical tissue agree well with this. In the absence of glucose the oxygen uptake and R.Q. are slightly decreased, which is in agreement with the observations of Dickens and Greville [1933, 1]. Results very similar to these were also obtained by Shorr

*et al.* [1930] using phosphate-Ringer solution as medium. Crabtree [1929], using phosphate-free Ringer solution, also found a slightly higher  $Q_{O_2}$  in the presence of glucose.

\* These values for  $Q_{O_2}$  appear higher than those of Gemmill and Holmes [1935]. This is probably due to the fact that the dry weights of tissue actually used were determined after each experiment. Gemmill and Holmes followed the perhaps more rational method of deducing the dry weight from the initial moist weight of the tissue used and the wet weight/dry weight ratio of a separate sample.

### *Tumours.*

The tumours studied were the Philadelphia No. 1 rat sarcoma [Waldschmidt-Leitz *et al.*, 1933] and the Walker No. 256 carcinoma. The tumours were taken 16–28 days after implantation and the slices used showed little or no necrosis. In Table VII are summarised the results of a large number of experiments, and results of specific experiments on the effect of glucose on the metabolism are given in Table VIII.

With Jensen rat sarcoma and a slow-growing carcinoma, Dickens and Šimer [1931] obtained mean R.Q. values of 0.78 and 0.77 in bicarbonate medium. The results here shown are, on the average, distinctly higher and our results differ sharply from theirs in that we have found a number of tumours with R.Q. values of about 1. The tumours showing this type of metabolism appeared quite normal,

had been growing rapidly and showed the usual high aerobic glycolysis. Further, one such tumour was used in the work reported in the preceding paper [Elliott *et al.*, 1935, Table VIII] and the deficiencies in metabolism seemed the same as with tumours with a lower R.Q. High values of R.Q. for tumour tissues have recently been reported by Jares [1935]. Using phosphate-buffered Locke solution as medium he found R.Q. 0.99 for a slow-growing Jensen sarcoma, 0.97 for a No. 180 mouse sarcoma, and for the No. 256 carcinoma he gives results up to 0.95 with a mean value of 0.89. Dickens and Šimer [1930] themselves observed quite high values of R.Q. in phosphate-Ringer medium with a slow-growing rat sarcoma (0.97), with the Rous chicken sarcoma (0.92), with a spontaneous mouse tumour (0.91) and with a human tumour (0.86).

It is interesting to note that with Phila. No. 1 tumour the respiration is slightly greater in the absence of glucose than in its presence, but that glucose does cause a slight rise in R.Q. These points are shown in Table VIII and in the average results in Table VII. Crabtree [1929] also showed increased  $O_2$  uptake in the absence of glucose with tar carcinoma 2146 and Jensen rat sarcoma, though Dickens and Greville [1933, 1] did not find this. Crabtree drew "the tentative conclusion that glycolytic activity exerts a significant checking effect on the capacity for respiration of tumour tissue". The effect of glucose on R.Q. would suggest that to a certain extent the sugar also replaces other substances as respiratory substrate.

#### DISCUSSION.

A summary of the R.Q. of the various tissues in the presence of glucose is given in Table IX.

The results here reported agree with those of Dickens and his co-workers in many details but in the following important respects the observations differ from those of Dickens and Šimer [1930; 1931]. For brain and retina they gave R.Q. 1 while our results are lower than this. For liver R.Q. 1 has frequently been found which is higher than any reported by other authors. For tumour also

Table IX. R.Q. in presence of glucose.

Animal	Tissue	No. of exps.	R.Q.		Mean
			Highest	Lowest	
Rat	Brain—grey matter	13	0.93	0.78	0.86
Rat	Retina	5	0.96	0.87	0.91
Rat	Testis	4	0.95	0.91	0.94
Rat	Kidney cortex	7	0.90	0.78	0.85
Rat	Liver of fed animals	78	1.15	0.70	0.94
Rat	Phila. No. 1 sarcoma	28	1.06	0.72	0.89
Rat	Walker No. 256 carcinoma	2	0.89	0.84	0.87
Rabbit	Brain—grey matter	4	0.95	0.83	0.88
Rabbit	Kidney cortex	9	0.92	0.85	0.88
Mouse	Liver of fed animals	9	0.99	0.64	0.78
Chick	Embryo	2	1.05	0.99	1.02

many of the results here given are higher than those of Dickens and Šimer and again several values of R.Q. of about 1 have been found. Consideration of their results led Dickens and Šimer to make the generalisation that all normal tissues which showed high glycolytic activity anaerobically respired in the presence of oxygen at R.Q. 1. The main respiratory activity of such tissues appeared therefore to consist in carbohydrate combustion, or oxidation of the lactic acid or some precursor, whilst under anaerobic conditions lactic acid accumulated. They found that tumour tissue, in spite of having a very high glycolytic activity, respired at a moderately low R.Q. and this was adduced as evidence that a failure to oxidise carbohydrate (or lactate) was characteristic of tumour tissue. The foregoing paper [Elliott *et al.*, 1935] shows that there is a definite failure by tumour tissue to oxidise carbohydrate by way of lactate and this fits in well with the conclusion of Dickens and Šimer. Nevertheless the findings of this paper show that consideration of R.Q. gives no evidence of abnormal failure of tumour tissue to oxidise carbohydrate. Though the R.Q. of most tissues seems to vary considerably, Table IX shows that there is no significant difference between the mean values for tumour and any other type of adult tissue. Further, in several cases with apparently typical tumours, R.Q. values of about 1 were obtained which would indicate carbohydrate oxidation. Oxidation of protein, with  $\text{NH}_3$  as end product instead of urea, involves R.Q. about 1, but consideration of the determinations of  $Q_A$  and  $Q_{LA}$  of Elliott *et al.* [1935] makes it seem unlikely that appreciable amounts of a base are being produced, and estimations by Dickens and Greville [1933, 2] of  $\text{NH}_3$  formation by the Jensen rat sarcoma indicated that very little protein is oxidised when glucose is present. The fact that the R.Q. of tumour is somewhat higher in the presence of glucose than in its absence also indicates that tumour tissue does oxidise carbohydrate. Nevertheless, if carbohydrate is oxidised by tumour, the course of breakdown must follow a route other than that involving lactic acid [Elliott *et al.*, 1935].

#### SUMMARY.

A study of the metabolism of various tissues has been made with particular reference to the R.Q., and the results obtained differ in important respects from those of Dickens and Šimer [1930; 1931]. In particular, the R.Q. values of brain (grey matter) and retina have been found to be less than 1, whilst with liver and tumour tissue R.Q. values of unity have frequently been observed. The main results are summarised in Table IX. It is concluded that there is no significant difference between the mean R.Q. of the different tissues of well-fed adult animals and that no evidence for defective carbohydrate oxidation by tumours can be adduced from consideration of R.Q.

# CCXC. A MODIFIED NESSLER'S REAGENT FOR THE MICRO-DETERMINATION OF UREA IN TUNGSTIC ACID BLOOD FILTRATE.

By JOHN FREDERICK BARRETT.

*From the Courtauld Institute of Biochemistry, Middlesex Hospital, London, W. 1.*

*(Received September 12th, 1935.)*

THE usual method for the determination of urea in blood is to decompose the urea with urease and then to remove the liberated ammonia from the solution by aeration or distillation. Such processes, especially when applied to fingerprick quantities (0.2 ml.) of blood, are laborious and involve the possibility of loss of ammonia or the introduction of ammonia present in the reagents. Hence it is not surprising that many chemists have attempted to determine the ammonia by direct nesslerisation of blood filtrates. Feinblatt [1923] and Karr [1924] described micro-methods in which urease was allowed to act on whole blood. Finally, the ammonia was determined by direct nesslerisation of a trichloroacetic acid filtrate. Peters and Van Slyke [1932] found that this method gave results from 2 to 7 mg. of urea per 100 ml. of blood higher than those obtained by aeration. In this country, Archer and Robb [1925] evolved a similar method, using tungstic acid as protein precipitant.

Such methods yield high results, because blood filtrates contain substances other than urea or ammonia which give an appreciable colour with Nessler's reagent, and secondly, the final solution becomes turbid on standing for a few minutes. Van Slyke and Cope [*v.* Peters and Van Slyke, 1932, p. 935], using a zinc filtrate, found that the addition of a little powdered sodium citrate to the filtrate prior to nesslerisation retarded the onset of turbidity and pointed out that citrate, instead of oxalate, should be used to prevent coagulation of the blood. The view advanced in this paper is that the interfering substances, which cause the increased colour and the ultimate turbidity of the solution, are reducing agents. Nessler's reagent may be considered to be an alkaline metal solution and is reduced at room temperature by small quantities of glucose, creatinine and other reducing substances present in the blood. The addition of Nessler's reagent to a creatinine solution of the concentration in which it is supposed to occur in blood filtrate produces, primarily, a yellow colour. This deepens and a turbidity gradually appears. Glucose, in blood filtrate concentration, gives a similar reaction.

When blood filtrate is treated with Nessler's reagent an exactly parallel series of changes takes place, *i.e.* a yellow coloration followed in a few minutes by marked turbidity.

Reducing substances other than those which occur in blood effect similar changes. Thus, a very dilute solution of formalin shows the same behaviour as creatinine or glucose.

When a suitable oxidising agent such as sodium hypochlorite, sodium persulphate or iodine is added to Nessler's reagent, the resulting solution is not affected by reducing substances. Sodium hypochlorite has been used as the oxidising agent in these experiments. It is probable that the primary action of

the oxidising agent is to produce hypoiodous acid from the constituents of the Nessler's reagent, because when, after standing, the modified reagent has become inactive, free iodine can still be detected if the reagent be acidified.

Glucose, creatinine and formalin in weak solutions give no colour or turbidity with the Nessler-hypochlorite reagent. Tungstic acid filtrate, containing a small quantity of sodium citrate, when treated with this modified reagent, is difficult to distinguish from the same quantity of water similarly treated. In the absence of hypochlorite, a marked change occurs in a few minutes in blood filtrate treated with Nessler's reagent.

The method described in this paper requires 0.2 ml. of blood, but the modified Nessler's reagent may be applied to a 1 in 10 filtrate obtained by treating larger quantities of blood with urease. Similarly, ordinary filtrate may be treated with buffer and urease and finally nesslerised in the presence of gum ghatti. Other applications are to be found in the nesslerisation of filtrates in which the urea has been hydrolysed by treatment with acid under pressure and in the direct determination of urea in urine.

The urease employed for the decomposition of urea in small quantities of blood must be free from ammonia and other substances which affect the colour or stability of the final solution. A simple method of preparing purified urease is to precipitate it from aqueous extract of jack bean with dilute acetic acid. The precipitate, centrifuged down and freed from the supernatant liquid containing ammonia and other impurities, is ready for use when redissolved.

#### METHOD.

##### *Reagents.*

(1) Standard ammonium sulphate containing 1.833 mg. of pure ammonium sulphate per 100 ml. This is conveniently prepared from a stronger stock solution.

(2) Nessler-hypochlorite reagent. Add 0.1 ml. of sodium hypochlorite, containing 10–13% available chlorine, to 20 ml. of Nessler's reagent [Koch and McMeekin, 1924] in a beaker. This solution, which is light yellow in colour, should be freshly prepared before use.

(3) 5% sodium tungstate.

(4)  $N/3$  sulphuric acid.

(5) Sulphate-tungstate mixture. Dissolve 5 g. of anhydrous sodium sulphate in water, add 15 ml. of 5% sodium tungstate and dilute to 1 litre.

(6) Urease solution. Suspend 1 g. of "Arleo"<sup>1</sup> jack bean meal in 50 ml. of water. Shake for several minutes and filter. If the first few drops are not clear, return the filtrate to the paper. This stock solution will keep for several days in the refrigerator. To prepare the purified urease, place 10 ml. of the extract in a centrifuge-tube, add two drops of 10% acetic acid and centrifuge for a few minutes. Discard the supernatant fluid and thoroughly mix the residue with about 2 ml. of sulphate-tungstate solution. Dilute with the same solution to 10 ml. to dissolve the urease.

(7) 1.5% sodium citrate.

*Procedure.* Transfer 1.0 ml. of urease solution to a 15 ml. conical centrifuge-tube. Add 0.2 ml. of blood, washing out the pipette in the solution. Stopper the tube and keep it in a beaker of water at 30° for 15 min. Add 5 ml. of water and 0.5 ml. of  $N/3$  sulphuric acid. Finally add 0.5 ml. of sodium tungstate, mix well and centrifuge for 5 min. Using a 5 ml. pipette, which is pressed by the finger against the wall of the tube so that the tip of the pipette is about 2 mm.

<sup>1</sup> Obtainable from Messrs Baird and Tatlock, Ltd., London.

above the protein precipitate, withdraw 5 ml. of clear supernatant fluid and transfer it to a 6 × 1 in. test-tube. Add 5 ml. of water and 0.5 ml. of sodium citrate followed by 1 ml. of Nessler-hypochlorite solution. The last reagent should be added rapidly whilst rotating the liquid in the tube. Compare the solution with the nearer standard in the colorimeter.

*Standards.* Transfer 5 and 10 ml. of standard ammonium sulphate to two 6 × 1 in. tubes and add 5 ml. of water to the first tube. Add citrate and Nessler-hypochlorite reagent as to the unknown.

*Calculation.* If the standard be set at 20 mm. and the reading of the unknown be  $R$  mm. then

$$\frac{600}{R} = \text{mg. of urea per 100 ml. of blood using the low standard;}$$

$$\frac{1200}{R} = \text{mg. of urea per 100 ml. of blood using the high standard.}$$

The following points should be observed:

(a) Fresh blood should be employed. Ammonia and products of protein digestion develop in blood on standing.

(b) Solutions should be well cooled prior to nesslerisation.

(c) If the reading of a blood urea be far from that of the nearer standard, a more appropriate standard should be prepared. It is advisable to repeat such determinations, however, using a more suitable quantity of blood. Two standards of values 30 and 60 mg. of urea per 100 ml. of blood have been employed since, by this means, the majority of blood ureas can be determined without repetition.

In Table I are shown figures comparing the direct micro-method with the aeration technique [*v.* Beaumont and Dodds, 1934, p. 418] carried out on tungstic acid filtrate.

Table I.

Specimen	Aeration (mg. urea/100 ml. of blood)	Direct nesslerisation (mg. urea/100 ml. of blood)
A	19.5	20.0
B	36.3	36.5
C	44.7	45.6
D	61.0	61.4
E	151	148
F	506	512

The recovery of ammonia added to 1 in 10 tungstic acid filtrate is shown in Table II. In these experiments 0.075 mg. of ammonia-nitrogen was added to 5 ml. of blood filtrate, which after nesslerisation and dilution to 25 ml. was compared with a standard containing 0.075 mg. of ammonia-nitrogen. It should be

Table II.

Specimen	Colorimetric reading in mm.
1	19.5
2	19.8
3	20.1
4	19.6
5	19.9
6	21.0

pointed out that urea reduces the colour produced by Nessler's reagent with ammonia. This effect is small with normal levels of blood urea but in specimen 6 the urea was over 500 mg. per 100 ml. of blood. Naturally this urea is removed

by urease in an actual determination. The influence of amino-acids and peptones [Folin and Wu, 1919] in the filtrate from fresh blood appears to be negligible from a clinical viewpoint.

Taking into account the small quantity of ammonia normally present in blood, it is seen that the added ammonia is quantitatively recovered within experimental error.

#### SUMMARY.

Substances which interfere with direct nesslerisation of blood filtrates are reducing substances. Glucose, creatinine and other reducing substances act on Nessler's reagent at room temperature producing a yellow solution and ultimately a turbidity. If an oxidising agent, such as sodium hypochlorite, be added to Nessler's reagent, the reducing substances no longer exert their effect. Based on this principle, a simple micro-method is described for the determination of urea in blood. Results obtained by this method agree closely with those obtained by aeration.

I wish to express my thanks to Prof. E. C. Dodds for his kindness in allowing me to carry out this work.

## CCXCI. THE FORMATION OF HYDROGEN FROM GLUCOSE AND FORMIC ACID BY THE SO-CALLED "RESTING" *B. COLI*. II.

By ABEL TASMAN.

*From the National Institute for Public Health, Utrecht, Holland.*

(Received July 26th, 1935.)

In the first communication on this subject [Tasman and Pot, 1935] a critical examination was made of the relevant publications of Stickland [1929], Stephenson and Stickland [1931; 1932: 1933] and Yudkin [1932], and this examination was supported partly by theoretical considerations and partly by experimental data. As regards the latter, briefly, Tasman and Pot did not succeed in preparing suspensions of *B. coli* by the method employed by the English investigators, which would liberate gas in the anaerobic fermentation of glucose but not from sodium formate. If the bacterial suspension in question was prepared by previous cultivation in or on caseinogen-peptone, the formation of gas ( $H_2 + CO_2$ ) from both glucose and sodium formate was parallel.

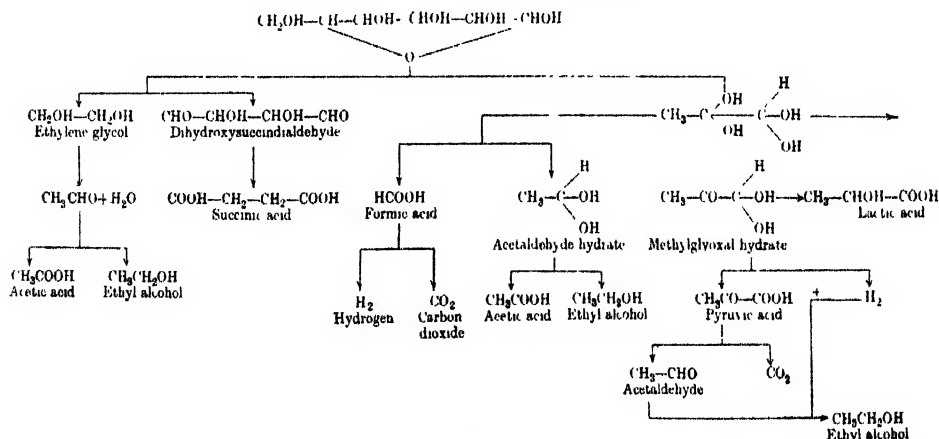

We also concluded that the hydrogen formed in the fermentation of glucose originated, in the majority of cases, from formic acid produced as an intermediate in the decomposition of this sugar.

As a continuation of these qualitative tests, experiments are described in this communication in which the fermentation of glucose, especially as regards the formation of hydrogen and carbon dioxide, has been investigated quantitatively.

Kluyver [1931: 1935] and his co-workers, amongst whom Scheffer [1928] warrants particular mention, have drawn up a general reaction scheme for the fermentation of glucose by microorganisms of the coli-typhosus-dysentericus group, which is reproduced below in abbreviated form.

*Synopsis of the reactions taking place in the fermentation of glucose by B. coli.*

(Abbreviated according to Scheffer.)

A discussion of the arguments which have led up to this reaction scheme will be omitted here; for this reference may be made to the publications of the authors mentioned above. Further discussion will be limited to a few practical consequences.

Methylglyoxal hydrate, which occupies a central position in this scheme, may decompose further in three different ways, namely, by:

- (a) isomerisation to lactic acid;
- (b) decomposition to pyruvic acid and hydrogen;
- (c) fission into formic acid and acetaldehyde hydrate.

The pyruvic acid mentioned under (b) will break down further into acetaldehyde and carbon dioxide, after which this acetaldehyde will be reduced to ethyl alcohol by the hydrogen liberated in the formation of pyruvic acid. In all the cases we have investigated the fermented substrates have given a negative Voges-Proskauer reaction, so that the formation of acetylmethylcarbinol and 2:3-butyleneglycol may be left out of consideration. The decomposition of glucose represented under (b) is usually termed the "pyruvic acid scheme".

If fission of methylglyoxal hydrate takes place *via* formic acid (by the so-called "formic acid scheme"), a more or less considerable proportion of the latter will be decomposed into equivalent amounts of hydrogen and carbon dioxide, whilst the acetaldehyde produced along with the formic acid will be converted into equivalent amounts of acetic acid and ethyl alcohol.

If as in alcoholic fermentation the decomposition of glucose more or less follows the "pyruvic acid scheme", neither hydrogen and carbon dioxide nor acetic acid and ethyl alcohol will be formed in equivalent quantities, but the ratio of hydrogen to carbon dioxide must be equal to that of acetic acid to alcohol, unless no hydrogen whatever is produced. Since in this case the hydrogen formed only in the decomposition to pyruvic acid is completely used up for the reduction of acetaldehyde to ethyl alcohol, the surplus alcohol, *i.e.* the number of g.mols. of ethyl alcohol *minus* the number of g.mols. of acetic acid, must be equal to the number of g.mols. of carbon dioxide formed by the decomposition of pyruvic acid, provided that the latter is completely decomposed. Since pyruvic acid was never encountered among the products of fermentation, this may be safely assumed. From the sequel it will appear that under certain conditions this is indeed the case.

As regards the formation of succinic acid, it is assumed that this compound is produced directly from glucose by decomposition of the sugar molecule into two shorter chains containing two and four carbon atoms respectively. The arguments for this method of representation must also be omitted here.

That this fermentation scheme is a possible one has been shown by the various investigators. At this stage it is not proposed to go any more deeply into the matter than to indicate the two primary requirements of the scheme.

1. The sum of the carbon in the various decomposition products calculated as percentages on the carbon originally present in the fermented glucose must add up very nearly to 100.

2. Primarily 1 g.mol. of glucose affords 2 g.mol. of methylglyoxal hydrate. If the "formic acid scheme" is followed these 2 g.mol. of methylglyoxal hydrate are converted into 2 g.mol. of formic acid and 2 g.mol. of acetaldehyde hydrate, from which (assuming that the formic acid is completely decomposed) finally, 2 g.mol. each of carbon dioxide, hydrogen, acetic acid and alcohol will be produced.

If the "pyruvic acid scheme" is followed, 2 g.mol. of methylglyoxal hydrate are converted into 2 g.mol. of pyruvic acid and 2 g.mol. of hydrogen,

the pyruvic acid producing subsequently 2 g.mol. of carbon dioxide; the hydrogen, as in alcoholic fermentation, is used up in the reduction of acetaldehyde, formed as an intermediate, to ethyl alcohol.

As a matter of fact, however, the whole of the formic acid is never converted into hydrogen and carbon dioxide and some can be recovered after the fermentation. At the same time, part of the methylglyoxal hydrate is stabilised by conversion into lactic acid. The line of thought sketched very briefly above is sufficient to allow of the probability of the "reaction scheme" being tested against the experimentally observed facts by calculating the quantities of the products obtained at the conclusion of the experiment to corresponding amounts of hydrogen, carbon dioxide and acetaldehyde. If the scheme is "correct", then these quantities must be such that 100 g.mol. of hydrogen, carbon dioxide and acetaldehyde must correspond with 50 g.mol. of fermented glucose. In this calculation:

1 g.mol. of unchanged formic acid corresponds to 1 g.mol. of hydrogen *plus* 1 g.mol. of carbon dioxide;

1 g.mol. of ethyl alcohol will equal 1 g.mol. of acetaldehyde *plus* 1 g.mol. of hydrogen;

1 g.mol. of acetic acid will equal 1 g.mol. of acetaldehyde *minus* 1 g.mol. of hydrogen;

1 g.mol. of lactic acid will represent 1 g.mol. of acetaldehyde *plus* 1 g.mol. of hydrogen *plus* 1 g.mol. of carbon dioxide.

As regards the succinic acid, which occurs in the fermentation, this is considered to result from the direct degradation of glucose without previous phosphorylation. The glucose consumed in this manner will be prevented from taking part in any subsequent fermentation. To test the correctness of this assumption it is necessary for each g. of succinic acid formed to subtract  $\frac{180}{118} \times 1$  g. from the amount of glucose decomposed during fermentation and to consider the remainder as "fermented glucose" in the above calculations. At the same time, 1 g.mol. of acetaldehyde for each g.mol. of succinic acid formed must be subtracted from the acetaldehyde balance, since acetaldehyde is formed along with succinic acid and is found in the final products of the fermentation either as alcohol or acetic acid, both of which appear in the acetaldehyde balance.

It needs hardly to be said that all these considerations only lead to a greater or smaller degree of probability of a given reaction-scheme. It is obvious that they do not form an exact proof of it.

For comparison, a few fermentations of glucose were carried out with growing *B. coli* cultures as well as with suspensions of "resting" *B. coli*. These fermentations took place under strictly anaerobic conditions in a caseinogen-peptone solution diluted with twice its volume of 0.5% sodium chloride solution. The original, undiluted caseinogen-peptone (again prepared according to Stickland's recipe [see Cole and Onslow, 1931]) presented considerable difficulty in the analyses of the fermented substrates. Since these experiments were carried out exactly as described in detail in earlier work, a reference to the relevant publication will suffice [Tasman and Pot, 1935]; here it need only be mentioned that 2% glucose was always used and 2% of previously sterilised chalk was added to fix the acids formed during fermentation.

Fermentations of glucose with *B. coli* suspensions were carried out as follows. 4.00 g. of glucose were weighed out and dissolved in 400 ml. of a phosphate buffer solution,  $p_H$  6.2, in a pyrex flask with an external mark at 750 ml. The flask was closed by a doubly bored rubber stopper carrying a dropping funnel with a long stem reaching into the liquid and a rectangularly

bent exit tube also fitted with a tap. The dropping funnel and the exit tube were made germ tight by means of cotton-wool plugs. The contents of the flask were sterilised in the usual way for 12 min. at 115°, the dropping funnel being closed and the exit tube open. Directly after sterilisation, the second tap was closed and the flask connected, while still hot, to a cylinder of nitrogen. The nitrogen was freed completely from oxygen by passage through alkaline pyrogallol solution. Thus during the cooling, the flask filled itself with nitrogen. It was then placed in a thermostat at 40° and the exit tube connected with a train of three calcium chloride tubes followed by three tared soda-lime tubes. The gases passing from the soda-lime tubes were collected in a measuring cylinder over paraffin oil.

The bacterial cultures were centrifuged, those from liquid media directly, and those from solid media after previously shaking with salt solution, washed twice with saline and suspended in 200 ml. of phosphate buffer solution previously boiled to free it completely from carbon dioxide. This suspension was then introduced into the fermentation flask *via* the dropping funnel and the bulb of the latter washed out with 100 ml. of boiled phosphate buffer solution. When temperature had reached equilibrium, the paraffin was sucked into the measuring cylinder and the contents of the flask were periodically shaken. Fermentation of the glucose set in rapidly and was usually complete in about 5 hours, during which time usually not more than about 1.8 g. of glucose were fermented. The cause of this appears to lie in the fact that the  $p_H$  of the buffer solution falls to about 4.4–4.9 owing to the formation of the various acids (formic, acetic, lactic, succinic) during fermentation. For all practical purposes, glucose is no longer fermented at these low hydrogen ion concentrations. This fact is in complete agreement with the phenomena observed by Stephenson and Stickland. Since, however, the idea was to obtain glucose fermentation by "resting" *B. coli* under as nearly as possible the same conditions as in the experiments of Stephenson and Stickland, the addition of chalk was dispensed with, although without doubt this would have ensured the fermentation of greater amounts of glucose. Also since fermentation took place at different rates in the different experiments, analyses of the substrate were always carried out about 18 hours after the commencement of fermentation.

As regards the methods of analysis employed for the various glucose fermentations, reference may be made to an earlier paper on this subject [Tasman and Pot, 1934]; attention will be drawn here to a few particulars only.

The mixtures obtained by fermenting with suspensions were first of all freed from bacteria before the analysis by centrifuging for an hour.

In peptone fermentations the total *volatile acids* (acetic and formic acids) were determined in the way already described, but in fermentations with suspensions 200 ml. of clear, centrifuged liquid were submitted to a fractional steam-distillation, in which six 250 ml. fractions were collected and titrated separately, the titration of the last fraction giving the blank titration by which each previous titration of 250 ml. had to be reduced. The whole six fractions were evaporated down to about 50 ml. after the titrations and the formic acid was determined in the usual way by the calomel method.

The *alcohol determination* in fermented caseinogen-peptone substrates was carried out in liquid which had been previously freed from peptones by precipitation with phosphotungstic acid, since determinations made in untreated substrates gave too high results.

Since phosphoric acid is noticeably soluble in ether, the residue from the steam distillation was precipitated with magnesia mixture to free it from phosphates

prior to being evaporated down for the determination of lactic and succinic acids.

*Lactic acid* was determined by the method of Friedemann and Kendall, details of which have been published previously, in peptone fermentations, but with suspensions the oxalic acid method of Ulzer and Seidel was used [Tasman, 1932].

It is of course obvious that the same limits of accuracy cannot possibly be reached in the analytical results on fermentations with suspensions as are obtained in the case of fermentations with growing bacteria. In the first case, only about 1.5 g. of glucose are fermented against 20–35 g. in the second group of fermentations. Thus the fact, that in some cases the results are extremely good and the hydrogen/carbon dioxide and acetic acid/alcohol ratios, for example, are in remarkable agreement, will certainly be due more to accident than to actual experimental accuracy. This holds especially for determinations of acetic acid, formic acid and carbon dioxide, which certainly do not reach a high degree of accuracy in suspension fermentations.

Most of the fermentation experiments were carried out in duplicate. In order to save space, however, only one example of each type of glucose fermentation will be given.

#### I. *Fermentation of glucose by growing B. coli in caseinogen-peptone.*

These were carried out with strains 1452 and "Stickland", which were always kept on caseinogen-peptone-agar. The results of these experiments are collected together in Tables I and II.

A consideration of these results shows that both fermentations agree completely with those described by Scheffer for *B. coli* and by Tasman and Pot for strains of *B. paratyphosus*. The fermentation takes place chiefly *via* the "formic acid" route, while, more particularly in the case of the fermentation of glucose by the "Stickland" strain, the "pyruvic acid scheme" is followed to some extent. Thus it appears that the hydrogen comes in all probability chiefly from formic acid formed as an intermediate, along with a small amount from the decomposition of methylglyoxal hydrate into pyruvic acid and hydrogen.

Table I.

*B. coli* 1452. Growing in dilute caseinogen-peptone.

Products	g.	% of carbon in the products, calculated on the carbon present in the glucose fermented	g.mol. per 50 g.mol. fermented glucose. 5.54 g. of glucose and 8.9 g.mol. of acetaldehyde subtracted for each 3.63 g. of succinic acid		
			Hydrogen	Carbon dioxide	Acet-aldehyde
Added glucose	36.60	100			
Glucose recovered	0.02				
Fermented glucose	36.58				
Hydrogen	0.220	—	31.9	—	—
Carbon dioxide	5.43	10.1	—	36.2	—
Acetic acid	4.88	13.3	23.6	—	23.6
Formic acid	0.232	0.4	1.5	1.5	—
Ethyl alcohol	4.25	15.2	26.8	—	26.8
Lactic acid	15.6	42.7	50.2	50.2	50.2
Succinic acid	3.63	10.1	—	—	— 8.9
Total		91.8	86.8	87.9	91.7

Hydrogen/carbon dioxide = 0.89. Acetic acid/ethyl alcohol = 0.88.

Table II.

*B. coli* "Stickland". Growing in dilute caseinogen-peptone.

Products	g.	% of carbon in the products, calculated on the carbon present in the glucose fer- mented	g.mol. per 50 g.mol. fermented glucose. 1.36 g. of glucose and 3.1 g.mol. of acetaldehyde subtracted for each 0.89 g. of succinic acid		
			Hydrogen	Carbon- dioxide	Acet- aldehyde
Added glucose	34.60				
Glucose recovered	11.62				
Fermented glucose	22.98	100			
Hydrogen	0.125	—	26.2	—	—
Carbon dioxide	3.74	11.9	—	35.4	—
Acetic acid	2.98	13.2	-20.8	—	20.8
Formic acid	0.769	2.2	7.0	7.0	—
Ethyl alcohol	3.62	20.5	32.5	—	32.5
Lactic acid	11.0	47.9	50.9	50.9	50.9
Succinic acid	0.89	3.7	—	—	- 3.1
Total		99.4	95.6	92.3	101.1

Hydrogen/carbon dioxide = 0.74. Acetic acid/ethyl alcohol = 0.65.

For comparison with these glucose fermentations an experiment was carried out in 1% Witte peptone solution. In this case strain 3812 was used, which had never been cultivated on caseinogen-peptone (Table III).

Table III.

*B. coli* 3812. Growing in 1% Witte-peptone.

Products	g.	% of carbon in the products, calculated on the carbon present in the glucose fer- mented	g.mol. per 50 g.mol. fermented glucose. 3.02 g. of glucose and 6.9 g.mol. of acetaldehyde subtracted for each 1.98 g. of succinic acid		
			Hydrogen	Carbon- dioxide	Acet- aldehyde
Added glucose	34.89				
Glucose recovered	9.84				
Fermented glucose	22.05	100			
Hydrogen	0.338	—	69.0	—	—
Carbon dioxide	6.47	17.6	—	60.1	—
Acetic acid	7.12	28.5	-48.5	—	48.5
Formic acid	1.25	3.3	11.1	11.1	—
Ethyl alcohol	4.78	24.9	42.5	—	42.5
Lactic acid	3.28	13.1	14.9	14.9	14.9
Succinic acid	1.98	8.4	—	—	- 6.9
Total		95.8	89.0	86.1	99.0

Hydrogen/carbon dioxide = 1.15. Acetic acid/ethyl alcohol = 1.13.

From the above it appears that under these conditions the "formic acid scheme" is followed exclusively, whilst at the same time the relatively large amount of hydrogen and carbon dioxide which is formed is remarkable. Thus here the hydrogen is derived probably from the intermediate formic acid.

It is self-evident in the light of what has previously been stated, that in the three fermentation experiments mentioned above the formation of succinic acid can be explained by a fission of the glucose molecule into groups containing two and four atoms of carbon.

II. *Fermentation of glucose by "resting" B. coli in a phosphate buffer; the suspension prepared by partial anaerobic culture in liquid caseinogen-peptone.*

Subcultures of strains 1452 and "Stickland" were made in caseinogen-peptone. At the end of 24 hours 16 bottles of 1000 ml. capacity and each containing 500 ml. of caseinogen-peptone were inoculated with the subcultures, and after about 20 hours a suspension of this culture was made in the way mentioned previously and used for the glucose fermentation experiments. The results of these experiments are collected together in Tables IV and V.

Table IV.

*B. coli* 1452. Cultivation: partially anaerobic in liquid caseinogen-peptone. "Resting"  
*B. coli* suspension in phosphate buffer  $p_H$  6.2.

Products	g.	% of carbon in the products, calculated on the carbon present in the glucose fermented	g.mol. per 50 g.mol. fermented glucose. 0.49 g. of glucose and 22 g.mol. of acetaldehyde subtracted for each 0.32 g. of succinic acid		
Added glucose	4.00				
Glucose recovered	2.38				
Fermented glucose	1.62	100	Hydrogen	Carbon-dioxide	Acet-aldehyde
Hydrogen	0.010	—	41	—	—
Carbon dioxide	0.30	13	—	54	—
Acetic acid	0.17	10	— 22	—	22
Formic acid	0.014	0.6	2.4	2.4	—
Ethyl alcohol	0.18	14	31	—	31
Lactic acid	0.59	37	52	52	52
Succinic acid	0.32	20	—	—	— 22
Total		94.6	104.4	109.4	83

Hydrogen/carbon dioxide = 0.75. Acetic acid/ethyl alcohol = 0.72.

Table V.

*B. coli* "Stickland". Cultivation: partially anaerobic in liquid caseinogen-peptone. "Resting"  
*B. coli* suspension in phosphate buffer  $p_H$  6.2.

Products	g.	% carbon in the products, calculated on the carbon present in the glucose fermented	g.mol. per 50 g.mol. fermented glucose. 0.23 g. of glucose and 9.8 g.mol. of acetaldehyde subtracted for each 0.15 g. of succinic acid		
Added glucose	4.00				
Glucose recovered	2.62				
Fermented glucose	1.38	100	Hydrogen	Carbon-dioxide	Acet-aldehyde
Hydrogen	0.0039	—	16	—	—
Carbon dioxide	0.29	14	—	51	—
Acetic acid	0.056	4	— 7.2	—	7.2
Formic acid	0.0053	0.2	0.9	0.9	—
Ethyl alcohol	0.15	14	25	—	25
Lactic acid	0.74	51	64	64	64
Succinic acid	0.15	10	—	—	— 9.8
Total		93.2	98.1	115.9	86.4

Hydrogen/carbon dioxide = 0.29. Acetic acid/ethyl alcohol = 0.29.

The following may be concluded from these results. Strain 1452 in suspension, i.e. as "resting" *B. coli*, ferments glucose in practically the same way as

when growing bacteria are used and chalk is added to the medium to fix the acids which are produced (see Table I). At the most, rather more is decomposed according to the "pyruvic acid scheme". Yet even under these conditions it may be assumed that the greater part of the evolved hydrogen originates from formic acid produced during the fermentation of the glucose.

On the other hand, the "Stickland" strain behaves otherwise. Here, apparently, the "pyruvic acid scheme" predominates, since the ratios hydrogen/carbon dioxide and acetic acid/ethyl alcohol, which are remarkably closely equal to one another, deviate very considerably from unity. However, since very little formic acid remains in the substrate (compare glucose fermentations with aerobically grown cultures discussed below, Tables VII and VIII), it may be assumed that in these glucose fermentations the hydrogen liberated as gas may still have its origin in the intermediate product, formic acid.

### III. Fermentations of glucose by "resting" *B. coli* in phosphate buffers.

*Suspensions prepared by partially anaerobic culture in caseinogen-peptone plus 1% of glucose.*

In connection with the possibility that *B. coli* might be able to ferment glucose in another way if it were "adapted" to this purpose beforehand, strain 1452 was subcultured daily for a fortnight on slopes of caseinogen-peptone-agar to which 0.5% of glucose had been added. A glucose fermentation was carried out with a suspension of this culture prepared in the usual way by subculture in liquid caseinogen-peptone containing 1% of glucose, and the results are found in Table VI.

Table VI.

*B. coli* 1452. Cultivation: before the experiment the strain was subcultured daily for 14 days on caseinogen-peptone-agar containing 0.5% glucose. A suspension was then prepared by partial anaerobic cultivation in liquid caseinogen-peptone containing 1% of glucose. "Resting" *B. coli* suspension in phosphate buffer  $p_H$  6.2.

Products	g.	%	g.mol. per 50 g.mol. fermented glucose		
			Hydrogen	Carbon-dioxide	Acet-aldehyde
Added glucose	4.00				
Glucose recovered	2.65				
Fermented glucose	1.35	100			
Hydrogen	0.0086	—	20	—	—
Carbon dioxide	0.022	11	—	34	—
Acetic acid	0.082	6.1	— 9.3	—	9.3
Formic acid	0.0025	0.1	0.4	0.4	—
Ethyl alcohol	0.093	9.0	13	—	13
Lactic acid	1.0	75	74	74	74
Succinic acid	—	—	—	—	—
Total		101.3	107.1	108.4	96.3

Hydrogen/carbon dioxide = 0.84. Acetic acid/ethyl alcohol = 0.70.  $p_H$  of fermented liquid = 4.41.

When these figures are compared with those in Table IV, in which the corresponding glucose fermentation was carried out with the same strain which had not however been "adapted" to glucose, then the only difference which comes to light is the absence of succinic acid from the products of fermentation, while approximately twice the usual amount of lactic acid is formed. In agreement with this, the other products of fermentation were found in relatively smaller quantities.

In both cases, however, the hydrogen/carbon dioxide and the acetic acid/alcohol ratios are practically equal, so that here again it may be assumed with great probability that the gaseous hydrogen is liberated *via* formic acid.

IV. *Fermentation of glucose by "resting" B. coli in a phosphate buffer.*  
*Suspension prepared by completely aerobic culture*  
*on caseinogen-peptone-agar.*

Roux flasks were used for the preparation of the necessary bacterial material, each flask containing a layer of solidified caseinogen-peptone-agar (4% agar) which was inoculated with a culture in liquid caseinogen-peptone. The results of a glucose fermentation carried out with this suspension are given in Table VII.

Table VII.

*B. coli* 1452. Cultivation: completely aerobic culture on caseinogen-peptone-agar. "Resting"  
*B. coli* suspension in phosphate buffer  $p_H$  6.2.

Products	g.	% of carbon in the products, calculated on the carbon present in the glucose fermented	g.mol. per 50 g.mol. fermented glucose. 0.088 g. of glucose and 5.6 g.mol. of acetaldehyde subtracted for each 0.058 g. of succinic acid		
Added glucose	4.00				
Glucose recovered	3.12				
Fermented glucose	0.88	100	Hydrogen	Carbon-dioxide	Acet-aldehyde
Hydrogen	—	—	—	—	—
Carbon dioxide	0.047	3.6	—	12	—
Acetic acid	0.067	7.8	- 13	—	13
Formic acid	0.19	14	47	47	—
Ethyl alcohol	0.10	18	25	—	25
Lactic acid	0.49	55	61	61	61
Succinic acid	0.058	6.2	—	—	- 5.6
Total		104.6	120	120	93.4

Acetic acid/ethyl alcohol = 0.49.

Surplus ethyl alcohol =  $\frac{0.10}{46} - \frac{0.067}{60} = 0.00217 - 0.00110 = 0.00107$  g.mol.

Carbon dioxide produced =  $\frac{0.047}{44} = 0.00107$  g.mol.

V.P.—reaction negative.

$p_H$  of the fermented liquid = 4.75.

It is at once obvious that hydrogen formation is completely absent, which is contrary to the qualitative experiments described in the first communication (see the Table, Exps. 9 and 13, strain 1452). In how far the undoubtedly different conditions under which these experiments were carried out determined the results must be left to conjecture. It may be mentioned here, however, that in the series of experiments described previously the formation of hydrogen from glucose under these conditions was in no way regular (see Exp. 12 in which the bacteria were cultivated on caseinogen-peptone-agar (puriss. Grubler)).

Against the absence of hydrogen from the fermentation products, a relatively large amount of formic acid and a small amount of carbon dioxide must be noted. The question naturally arises as to where this carbon dioxide originates. From the fact that this *B. coli* strain, 1452, under all conditions follows the "formic acid scheme" to the greater extent, yet at the same time always follows the "pyruvic acid scheme" to a much less extent, it is obvious that the reason for

the formation of carbon dioxide in the case in question is to be sought in the decomposition of glucose in the latter way. If this supposition is correct, the whole of the hydrogen resulting from the decomposition of methylglyoxal hydrate must be completely used up in the reduction of acetaldehyde to alcohol. Consequently, the quantities of carbon dioxide and excess alcohol (*i.e.* alcohol *minus* acetic acid) formed must be equivalent when expressed in g.mol. This appears indeed to be the case. That these quantities are so nearly equal in this case must of course be ascribed to an accidentally very favourable analytical result.

The fact that the quantities of hydrogen and carbon dioxide occurring in the hydrogen-carbon dioxide-acetaldehyde balance deviate from 100 is caused in all probability by the formic acid determination giving too high results. The amount of glucose which undergoes fermentation is so small that the fermentation balance, based as it is on these analyses, cannot be very accurate and further explanation is unnecessary.

That so little glucose is fermented under these conditions readily finds an explanation in the fact that the formic acid formed is not decomposed further so that the hydrogen ion concentration falls much more rapidly to the fatal low limit than would otherwise be the case, which must again result in still less glucose being fermented.

V. *Fermentation of glucose by "resting" B. coli in a phosphate buffer.*  
*Suspension prepared by complete aerobic culture on caseinogen-peptone plus 0.5% of sodium formate.*

Finally, it was investigated how far a previous "acclimatisation" to formic acid under aerobic conditions would enable the bacterial suspension to decompose

Table VIII.

*B. coli* 1452. Cultivation: before the experiment the strain was subcultured daily for 14 days on caseinogen-peptone-agar containing 0.5% of sodium formate. A suspension was then made by complete aerobic cultivation on caseinogen-peptone plus 0.5% sodium formate. "Resting" *B. coli* suspension in phosphate buffer  $p_H$  6.2.

Products	g.	%	g.mol. per 50 g.mol. fermented glucose, 0.20 g. of glucose and 16 g.mol. of acetaldehyde subtracted for each 0.13 g. of succinic acid		
			Hydrogen	Carbon-dioxide	Acetaldehyde
Added glucose	4.00				
Glucose recovered	3.18				
Fermented glucose	0.82	100			
Hydrogen	—	—	—	—	—
Carbon dioxide	0.027	2.2	—	8.5	—
Acetic acid	0.080	9.8	-20	—	20
Formic acid	0.19	15	59	59	—
Ethyl alcohol	0.080	13	26	—	26
Lactic acid	0.41	50	66	66	66
Succinic acid	0.13	16	—	—	-16
Total		106	131	131.5	96

Acetic acid/ethyl alcohol = 0.75.

Surplus ethyl alcohol =  $\frac{0.080}{46} - \frac{0.080}{60} = 0.00174 - 0.00133 = 0.0041$  g.mol.

Carbon dioxide produced =  $\frac{0.027}{44} = 0.0061$  g.mol.

$p_H$  of the fermented liquid = 4.89.

glucose with the formation of hydrogen. For this purpose, strain 1452 was sub-cultured daily for a fortnight on caseinogen-peptone-agar plus 0.5% of sodium formate and inoculated into Roux flasks containing caseinogen-peptone-agar plus 0.5% of sodium formate *via* a passing subculture. The result of a fermentation carried out with this suspension is given in Table VIII.

From this result it appears that the "acclimatisation" did not have the desired effect. The experiment agrees essentially with those carried out previously. In this case also decomposition took place mainly *via* the "formic acid scheme" and only to a small extent *via* the "pyruvic acid scheme". Here again the hydrogen is in all probability used up completely in the reduction of acetaldehyde to ethyl alcohol, which follows from the fact that the values for the surplus alcohol and carbon dioxide formed are about equal when expressed in g.mol. That the agreement in this case is not so close as in the previous experiment needs no further explanation. The small amount of glucose undergoing fermentation is explained as mentioned earlier.

#### DISCUSSION.

Reviewing the whole of these experiments we find a quantitative confirmation of the experiments described in the first communication which were only of a qualitative nature, and little need be added to the conclusions formulated therein.

In conclusion, as regards the decomposition of glucose by *B. coli* under anaerobic conditions, it may be assumed that in the majority of cases this decomposition takes place *via* the "formic acid scheme" and the hydrogen liberated in the gaseous state is formed mainly by the decomposition of formic acid produced as an intermediate. Only in a few cases does the decomposition of glucose *via* the "pyruvic acid scheme" occur to a preponderating extent. The same remarks hold for fermentations of glucose both with living reproductive *B. coli* and in those cases where the glucose was fermented in a phosphate buffer at  $p_H$  6.2 with a suspension of "resting" *B. coli*. All the phenomena observed are in agreement with the reaction scheme put forward by Kluyver, Scheffer *et al.*, for the fermentation of glucose by members of the coli-typhosus-dysentericus group.

#### SUMMARY.

1. In connection with experiments on the formation of hydrogen and carbon dioxide in the fermentation of glucose by "resting" *B. coli*, which have been described in an earlier paper, experiments are described in the present communication in which glucose has been fermented under anaerobic conditions both by living reproductive *B. coli* and with suspensions of "resting" *B. coli*.

2. In the majority of cases, the glucose is decomposed mainly in conformity with the so-called "formic acid scheme", showing that in all probability the gaseous hydrogen produced in these cases is formed by the decomposition of formic acid, occurring as an intermediate, into equivalent amounts of hydrogen and carbon dioxide.

3. Only in a few cases is the glucose decomposed mainly in accordance with the so-called "pyruvic acid scheme". This is expressed in the fact that although the ratios hydrogen/carbon dioxide and acetic acid/alcohol are equal, they deviate considerably from unity.

4. All the observed facts appear to be in agreement with the reaction scheme for the fermentation of glucose put forward by Kluyver, Scheffer and their co-workers.

Finally, a word of thanks must be expressed to Dr A. W. Pot, who has very ably collaborated with me during the carrying out of this investigation.

# CCXCII. THE BEHAVIOUR OF PEPSIN IN THE ULTRACENTRIFUGE AFTER ALKALINE INACTIVATION.

By JOHN ST LEGER PHILPOT.

*From the Department of Physical Chemistry, Upsala, and the Department of Biochemistry, Oxford.*

*(Received September 17th, 1935.)*

## INTRODUCTION.

IN previous work [Philpot and Eriksson-Quensel, 1933] the behaviour of crystalline pepsin in the ultracentrifuge was shown to be that of a homogeneous substance of molecular weight about 35,000, with approximately spherical molecules. The work has now been extended to cover pepsin which has been inactivated by alkali.

The facts already known about alkaline inactivation are as follows [Northrop, 1930; Goulding *et al.*, 1927]:

(1) The change is very slow at  $p_H$  6 and increases in speed with  $p_H$  until at  $p_H$  9 it is practically instantaneous.

(2) Under the conditions used by Goulding *et al.* and by Northrop a definite fraction of the activity disappears instantaneously even at  $p_H$  6, and this fraction increases with  $p_H$ .

(3) When the  $p_H$  is brought back to below 6, up to 10% of the original activity can be restored. The optimum  $p_H$  for this reactivation is 5.4 [Northrop, 1931].

(4) Inactive pepsin is rapidly digested by active pepsin. This is probably one reason for the incompleteness of the reactivation.

The study of the changes in sedimentation constant accompanying the above changes is complicated by the fact that the solution in the ultracentrifuge is exposed for 1-3 hours to a temperature rising to 30-35° during the period of measurement. This makes it impracticable to distinguish "slow" from "instantaneous" inactivation at a  $p_H$  where both are supposed to occur: it is only possible to study the final result of the two processes and its dependence on  $p_H$ . It is also impracticable to study a solution containing a mixture of active and inactive pepsin at a  $p_H$  where digestion can occur. Further there is the problem of obtaining reproducible specimens of pepsin. Different ones used in this work had sedimentation constants varying from  $2.9 \times 10^{-13}$  to  $3.7 \times 10^{-13}$ . They must, therefore, have been slightly inhomogeneous, though this was not always apparent in the ultracentrifuge since with such small molecules slight inhomogeneity is obscured by diffusion. Also, although all the specimens were very well crystallised, the peptic activity as measured by the haemoglobin method varied between 60 and 80% of the highest activity recorded by Northrop. Nevertheless it has been possible to observe certain definite phenomena which seem worth recording.

## EXPERIMENTAL.

*Ultracentrifuge.* The work was done in Svedberg's laboratory at Upsala, using his oil-turbine ultracentrifuge [Svedberg, 1934], with the light absorption method of recording the sedimentation.

*Preparation of pepsin.* The crystalline pepsin was obtained by procedures slightly modified from that of Northrop [1930]. Each preparation had a slightly different history, as continual efforts were being made to improve the method. These intentional variations, together with unavoidable accidental ones, probably account for the variations in the final product which have already been mentioned. A perfect method of preparation has yet to be found, but the most promising one tried so far is as follows.

*First crystallisation.* Dissolve 100 g. Parke-Davis pepsin (1 : 10,000) in 100 ml.  $H_2O$  and add 100 ml.  $NH_2SO_4$ . Filter through a large finest grade sintered Jena glass filter ("25G4") to remove traces of an insoluble slimy substance. Add 200 ml. saturated  $MgSO_4$  through a capillary at a rate of 2 drops per second, using rapid mechanical stirring. (The slow regular addition gives a coarse granular precipitate which filters very easily.) Filter as above, removing as much mother-liquor as possible without letting the precipitate become dry. The moist precipitate weighs 50–70 g. according to the batch of starting material. Dissolve the precipitate, without washing, in a minimum volume of dilute acetate buffer (0.105  $M$   $CH_3COOH$ , 0.05  $M$   $NaOH$ ,  $p_H$  4.6). The volume required (ml.) is slightly less than the weight of precipitate (g.). Filter and leave to crystallise at room temperature, stirring mechanically at a rate just sufficient to prevent the crystals from settling out. Crystallisation is complete after 5–6 days: yield 10–18 g. moist crystals. The crystallisation can be hastened by using a higher temperature (e.g. 37°) but there is more decomposition. If the solution is not stirred it will deposit perfect crystals (about 1 mm. long) visible to the naked eye (some of these crystals were given to Bernal and Crowfoot [1934] for X-ray examination): but it will take a very long time to complete the crystallisation and the crystals will be stuck to the walls of the vessel.

*Recrystallisation.* Stir the moist crystals at room temperature for half an hour with acetate buffer of the same composition as above, but ten times as strong (i.e. 1.05  $M$   $CH_3COOH$ , 0.5  $M$   $NaOH$ ), using a volume of buffer (ml.) equal to 1.2 times the weight of moist crystals (g.). Filter from the undissolved matter, which should be very little. Add slowly, with stirring, a volume of  $NH_2SO_4$  equal to 0.45 times the volume of buffer taken. There should be no permanent precipitate: if there is the solution must be filtered and the residue discarded. Leave the clear solution to crystallise for 3 days at room temperature with slow mechanical stirring. Yield about 50%. Some of the pepsin used in the ultracentrifuge experiments had been recrystallised 2–3 times using the same dilute buffer as in the first crystallisation. The use of stronger buffer was introduced in order to obtain a pepsin concentration equal to that in the first crystallisation. Recrystallisation does not always increase the homogeneity or the specific activity and may even decrease it. The final product was sometimes dialysed against distilled water or dilute buffer to remove non-centrifugible matter.

*$p_H$  control.* A typical experiment involved bringing the  $p_H$  from 4.6 to 9 and back to 4.6 again. In doing this a compromise was made between the following mutually antagonistic principles:

- (1) The solution used for changing the  $p_H$  must differ in  $p_H$  as little as possible from the final value for the mixture. This is to avoid local extremes of  $p_H$  during mixing with possible production of irreversible changes in the protein.

- (2) The buffer concentration in the final mixture must be low enough to avoid large corrections for viscosity and density in calculating the sedimentation constant, because the final concentration of each form of buffer cannot always be accurately estimated.

(3) At all stages the buffer concentration must be high enough for the  $p_H$  to be easily controllable.

In practice the  $p_H$  of the added buffer differed from the value after mixing by about 0.5 unit, and the mixing was done as rapidly as possible by pouring from one test-tube to another. The final total buffer concentrations were about 0.1 *M*. The measured  $p_H$  was usually within 0.3 of that calculated by approximate equations, whilst the correction for viscosity and density was from 1 to 6% of the sedimentation constant. The buffers used were acetate, phosphate and borate, according to the  $p_H$ . In calculating the quantity of buffer required to change the  $p_H$ , allowance was made for other buffers present in the solution, but not for the protein since its concentration was very low (about 0.1%). The  $p_H$  values recorded were obtained by measurement with a hydrogen or glass electrode, or were calculated, in which case the uncertainty probably does not exceed 0.3 unit.

#### RESULTS.

1. *The variation of sedimentation constant with  $p_H$ .* Pepsin solutions were brought to various  $p_H$  values and ultracentrifuged at once. The measured sedimentation constant corresponds therefore to the condition of the substance after 1–2 hours at this  $p_H$ . The results are shown in Fig. 1. The data are in-

Fig. 1. The variation of sedimentation constant of pepsin with  $p_H$ .

complete; but there is no doubt that in the region 7–11 the sedimentation constant falls with increasing  $p_H$ . At  $p_H$  6–7, the region of "slow" inactivation, two different specimens gave quite different results. The curve has therefore been left undrawn in this region, as it requires much more detailed study. Even as

Fig. 2 a.

Fig. 2 b.

Fig. 2 c.

Fig. 2 d.

Fig. 2 e.

Fig. 2 f.

Fig. 2. Sedimentation diagrams of pepsin (for explanation see text). *a*, at  $p_H$  11; *b*, at  $p_H$  5; *c*, at  $p_H$  4.6 after standing at  $p_H$  6.7 for 10 min.; *d*, at  $p_H$  4.6 after standing at  $p_H$  6.7 overnight; *e*, at  $p_H$  4.5 after standing at  $p_H$  9 for 10 min.; *f*, at  $p_H$  4.0 after standing at  $p_H$  9 for 10 min.

far as  $p_H$  11 the protein remains surprisingly homogeneous, as is shown by the sedimentation diagram in Fig. 2*a*. For comparison Fig. 2*b* shows pepsin at  $p_H$  5.0 where no alkaline inactivation occurs. For contrast Fig. 2*c* shows a very inhomogeneous preparation which will be described later.

These sedimentation diagrams are obtained by photographing the solution in the ultracentrifuge with ultraviolet light at a series of instants from the start of sedimentation. The photographs are converted by means of a microphotometer into curves of which the abscissae are radial distances inside the ultracentrifuge cell and the ordinates are concentrations. The scales of ordinates and abscissae are arbitrary. If the protein is homogeneous there will be a sharp sedimentation boundary which will appear in each curve as a steep S-shaped portion with a nearly horizontal lower portion. Conversely a curve rising gently the whole way indicates inhomogeneity.

2. *The variation of sedimentation constant with final  $p_H$  of pepsin initially brought to  $p_H$  9.* Pepsin was brought to  $p_H$  9 and left for 10 min. at room temperature, which is sufficient for complete inactivation. It was then brought back to a  $p_H$  value ranging from 3.8 to 4.9. In Fig. 3 the sedimentation constant

Fig. 3. The variation of sedimentation constant with final  $p_H$  of pepsin initially brought to  $p_H$  9. Points bracketed together represent components co-existing in solution.

is plotted against the final  $p_H$ . At final  $p_H$  4.9 the sedimentation constant is slightly lower than that of normal pepsin. At final  $p_H$  4.8 about 30% is transformed into molecules having a sedimentation constant nearly four times that of normal pepsin. At final  $p_H$  4.7 the transformation is nearly complete. The sedimentation constant then rises with falling final  $p_H$ . There is pronounced inhomogeneity over the whole range, as is shown for instance in Fig. 2*e*, which

represents pepsin at a final  $p_H$  of 4.5. At final  $p_H$  4.0 there are three distinct components, as is shown in Fig. 2*f*; their sedimentation constants are respectively about 10, 20 and 25 times that of normal pepsin. This is the last stage before precipitation, which is complete at final  $p_H$  3.8.

3. *The variation of sedimentation constant with initial  $p_H$  of pepsin finally brought to  $p_H$  4.5.* Pepsin was kept at  $p_H$  values between 6.7 and 11.6 for 10 min. and then brought to  $p_H$  4.5. The results are shown in Fig. 4. Between initial

Fig. 4. The variation of sedimentation constant with initial  $p_H$  of pepsin finally brought to  $p_H$  4.5. Points bracketed together represent components co-existing in solution. The point enclosed in a bracket was obtained on standing at the initial  $p_H$  overnight instead of for 10 min.

$p_H$  7.9 and 11 the final sedimentation constant is surprisingly constant, being about 10 times that of normal pepsin. As the initial  $p_H$  falls an increasing portion of the material suffers a fall instead of a rise in sedimentation constant and becomes very inhomogeneous. This portion is about 16% at initial  $p_H$  7.9 and rises to 100% at initial  $p_H$  6.7 even if the final  $p_H$  is as low as 3.8. However, if the pepsin is left at initial  $p_H$  6.7 overnight the transformation to the higher sedimentation constant on bringing to  $p_H$  4.5 is complete. Fig. 2*c* shows the effect of 10 min. at initial  $p_H$  6.7. Not only is the mean sedimentation constant low, but the product is very inhomogeneous, probably through digestion of inactive by active pepsin. Fig. 2*d* shows the effect of 24 hours at initial  $p_H$  6.7. The sedimentation constant is now much higher (the curve was obtained at a much lower rotational velocity).

#### DISCUSSION.

The most surprising thing about the results here described is the homogeneity of alkali-inactivated pepsin. The inactivation is regarded by Northrop as a case of alkaline denaturation, but this is usually accompanied by the production of marked inhomogeneity. It might be better to say that alkali converts pepsin into another protein which is more easily denatured by acid, since the substance formed on returning to  $p_H$  4.5 is sufficiently inhomogeneous to be so regarded. The  $p_H$  at which this "acid denaturation" of alkaline pepsin begins, namely 4.8, is close to that found by Northrop [1931] to be the optimum for reactivation, namely 5.4. The optimum may therefore mean that reactivation can only proceed if the protein has not undergone "acid denaturation"; but it may merely be due to the more rapid digestion of inactive by active pepsin at lower  $p_H$ .

The changes in sedimentation constant admit of various interpretations. The slight fall on alkaline inactivation might be due to a change in molecular weight, in shape or in degree of hydration. The first might be detected by a determination of the sedimentation equilibrium. This has not yet been done. It should also be distinguishable through a rise in diffusion constant, whereas change in shape or increase in degree of hydration should cause a fall in diffusion constant. It has been found by Polsen (unpublished), in Svedberg's laboratory, that the diffusion constant falls. Thus the change is probably one of shape or degree of hydration. On the other hand the increase of sedimentation constant on "acid denaturation" of alkaline pepsin is so large that it must be due to aggregation. The fact that the sedimentation constant at a given final  $p_H$  is independent of initial  $p_H$ , as shown in Fig. 4, suggests that the  $p_H$  at which alkaline inactivation is performed has no fundamental influence on the nature of the final product.

#### SUMMARY.

1. When pepsin is brought to  $p_H$  7 or higher the sedimentation constant falls, although the protein remains homogeneous.

2. When pepsin so treated is brought back to  $p_H < 4.8$  a large rise in sedimentation constant occurs, and the protein becomes less homogeneous. The rise is greater the lower the final  $p_H$ , until at  $p_H$  3.8 the protein is completely precipitated. The rise is approximately independent of initial  $p_H$  between  $p_H$  6.7 and 11; but if the initial  $p_H$  is 6.7 it must be maintained for some time to be effective.

3. These results show that alkali-inactivated pepsin is distinguished by its homogeneity from "denatured" proteins; but that it has undergone some change which makes it more easily "denatured" by acid. They also suggest that the  $p_H$  at which alkaline inactivation is performed has no fundamental influence on the nature of the final product.

I am greatly indebted to Prof. Svedberg for allowing me to work in his laboratory, and for much helpful advice.

The cost of the ultracentrifugal determinations has been defrayed by grants from the Rockefeller Foundation and the Foundation "Therese och Johan Anderssons Minne".

# CCXCIII. CAROTENOIDS AND VITAMIN A IN COW'S BLOOD SERUM.

BY ALBERT EDWARD GILLAM AND MOHAMED SHAFIK EL RIDI.

*From the Chemistry Department, Manchester University.*

*(Received September 17th, 1935.)*

It has been shown that cow's blood serum [Fine, 1933] possesses the power of promoting growth when fed to rats on a vitamin A-free diet. Part at least of this activity must be due to carotene, which can act as a provitamin A [Euler and Hellstrom, 1928; Euler *et al.*, 1929] and, together with bilirubin, is mainly responsible for the golden yellow colour of blood serum [Palmer and Eccles, 1914; Palmer, 1922].

In addition to carotene the presence of vitamin A in blood serum has been demonstrated by means of the antimony trichloride blue test [Rosio, 1929; Eekelen, 1931; Euler and Virgin, 1932; Lundborg, 1933; Menken, 1934; Eekelen and Emmerie, 1935]. Rosenthal and Szilard [1935] have confirmed this by a test which is specific for the vitamin even in the presence of carotene [Rosenthal and Erdélyi, 1934, 1, 2]. Still further confirmation is supplied by the observation that an alcoholic extract of blood serum exhibits selective light absorption near  $325m\mu$  [Chevallier and Choron, 1934].

Since the blood serum of the cow must carry the carotenoids of the food (converted partially into vitamin A at some point on the journey) to the udder, and hence to the milk, we decided to determine the carotene and vitamin A in the blood sera of cattle for comparison with the values previously found for milk fat [Gillam *et al.*, 1933; Watson *et al.*, 1933; 1934].

The present paper records the results of a preliminary examination of a number of cow and bull sera using spectrophotometric methods for determination of both carotene and vitamin A.

## *Extraction of the unsaponifiable matter.*

100 ml. of the blood serum are heated on a water-bath (1 hour) with aqueous KOH (10 ml. 60%) [cf. Davis, 1933]. The mixture is cooled, treated with alcohol (30 ml.) and extracted with ether (50 ml.) four times. The combined ether extracts are washed with water and dried over sodium sulphate and the ether is removed in a stream of nitrogen. The residue is dissolved in chloroform and made up to 100 ml. When the quantity of serum available is limited, much smaller portions can be used if necessary.

## *Determination of the carotene and vitamin A.*

The absorption spectrum of the solution is now determined in the visible and ultraviolet (Spekker photometer and Hilger E 3 quartz spectrograph), the procedure being identical with that already described in detail in the case of butter [Gillam, 1934]. From the observed intensity of absorption of light at  $460m\mu$  the carotenoids present in the serum can be calculated as carotene, using the standard value of  $E_{1\text{cm.}}^{1\%} = 2200$  [Gillam, 1935]. ( $E_{1\text{cm.}}^{1\%} = \log \frac{I_0}{I}$  for a 1 cm. layer of 1% solution,  $I_0$  = intensity of incident light,  $I$  = intensity of transmitted light).

The light absorption at  $328m\mu$  is due to vitamin A *plus* carotene, but it has been shown that the value due to carotene at this wave-length can be obtained by dividing the observed intensity at  $460m\mu$  by the factor 6.5 [Gillam, 1934]. After this correction is applied to the gross absorption at  $328m\mu$  the vitamin A present is calculated in mg. per 100 ml. of serum from the equation  $\frac{E \times 1000}{16}$ , where  $E = E_{1\text{cm}}^{1\%}$  mentioned above. The resulting value is based on the assumption that pure vitamin A has a value of  $E_{1\text{cm}}^{1\%} = 1600$  [Carr and Jewell, 1933; cf. also Karrer and Morf, 1933].

In butter the amount of vitamin A present is such that its absorption band is often seen clearly in the absorption curve of the unsaponifiable matter. In blood serum, however, the vitamin A is commonly present in much smaller amounts and the absorption due to the vitamin, although obtainable by subtraction, is not readily seen. In order to test for vitamin A more definitely the light petroleum solution of the carotenoids obtained from 90 ml. of serum was extracted with 90 % methyl alcohol until no more colour was removed. By this means the vitamin A was freed from carotene and the absorption spectrum of the methyl alcohol solution now showed the characteristic vitamin A band at  $328m\mu$ , together with weakly defined absorption bands at 477 and  $447m\mu$ , associated with the yellow colour (see below).

The presence of vitamin A was further confirmed by the fact that, when transferred to chloroform and concentrated, the solution gave a blue colour with antimony trichloride, showing a clear absorption band at  $617m\mu$  and a subsidiary maximum at  $583m\mu$ , the intensity being much greater than could possibly be due to the small amount of carotenoid present.

The pigment responsible for the weak yellow colour of the methyl alcohol phase had the following properties:

- (a) hypophasic in 90 % methyl alcohol to light petroleum;
- (b) absorption maxima in chloroform at 488 and  $456m\mu$ ;
- (c) when mixed with carotene and adsorbed on alumina it showed itself as a lemon-yellow ring well above that of the carotene.

These properties agree with those of lutein and the amount present is of the same order as that found in butter, *i.e.* about 5 % of the total carotenoids [Gillam *et al.*, 1933; Gillam, 1934]. This is in agreement with the previously reported occurrence of small quantities of "xanthophyll" in blood serum [Palmer and Eccles, 1914].

In view of the fact that the lutein content of grass is twice that of the carotene, whereas in blood serum the latter constitutes nearly the whole of the carotenoids, it is clear that in the metabolism of the cow carotene is absorbed preferentially [cf. Zechmeister and Tuzson, 1934]. In the horse this selective absorption of carotene appears to be more nearly complete than in the cow and is probably effected by the walls of the gut [Zechmeister *et al.*, 1935].

By concentrating the carotene fractions from several litres of cow serum and using the adsorption method already applied to butter [Gillam and Heilbron, 1935] we have found that small amounts of kryptoxanthin occur occasionally in blood serum exactly as in the case of butter. The adsorption of blood serum carotene on alumina also shows the separation of pigment into red and yellow zones previously observed with butter [Gillam and Heilbron, 1935], these two zones exhibiting absorption maxima closely simulating those of  $\beta$ - and  $\alpha$ -carotene respectively.

Twenty-one samples of bovine blood sera falling approximately into two groups, which can be regarded as winter and summer samples respectively, were

examined. The results show that the average carotene and vitamin A contents of the sera of cows are consistently higher than those of bulls in both winter and summer, whilst the average values for the sera of cattle in winter are definitely lower than the corresponding ones obtained during the spring and summer.

These results, obtained by the more precise spectrophotometric methods, are in agreement with the findings of Rösio [1929] who, using the Lovibond blue test, has shown that species, age, sex and the presence or absence of gestation are important factors controlling the vitamin A and carotene contents of the sera of animals. Similarly, Lundborg [1933] has shown that the blood serum of the cow is several times richer in vitamin A than that of the ox.

It has been shown that access to carotene-rich fodder increases the carotene content of cow's blood serum, previously at a low level through poor feeding [Semb *et al.*, 1934], just as it does in the case of milk fat. These variations in the quality of the food eaten are undoubtedly the cause of the definitely higher values of the summer sera over those of the winter samples, and it is equally certain that the explanation of the exceptional cases in both the winter and summer groups (*cf.* Tables) is to be found in differences in diet. As, however, the samples examined here were only casual and nothing was known of the nutritional history of the cattle this is necessarily only conjectural until more carefully controlled experiments can be carried out.

#### SUMMARY.

An examination of the unsaponifiable matter of cow's blood serum shows that, in addition to the main pigment (carotene), there are also present a small amount of lutein and, as in the case of butter, casual traces of kryptoxanthin. Vitamin A is also present.

The carotene and vitamin A values of a number of samples of cow and bull sera have been determined spectrophotometrically. The results show that the cow sera are on the average several times richer in carotene and vitamin A than are those of bulls, and that both cow and bull sera usually contain more of these two constituents in summer than in winter.

Our thanks are due to Prof. I. M. Heilbron for his interest and advice, and to the University of Cairo for enabling one of us (M. S. R.) to participate in this work. Thanks are also due to Messrs Imperial Chemical Industries Ltd. for a grant which has enabled Mr G. V. Cawthorne to render much help with the practical work.

## CCXCIV. A NOTE ON A SYNTHETIC DIET FOR RABBITS.

By REGINALD PASSMORE.

*From the Department of Biochemistry, Oxford.*

*(Received September 23rd, 1935.)*

THE diet of rabbits normally contains large amounts of cellulose, and the main problem in preparing a suitable synthetic diet is to obtain a palatable form of this constituent. Woodward and McCay [1932] reported the use of regenerated cellulose, and a commercial product, "Diophane",<sup>1</sup> has been used by us throughout. It was first washed thoroughly for twenty-four hours to remove glycerol, then pressed dry and ground as finely as possible. The diet was made up as follows: "Diophane" 300, corn starch 200, caseinogen 120, sucrose 80, butter 100, marmite 90, salt mixture 50 and ascorbic acid 0.1. The salt mixture consisted of sodium bicarbonate 152, magnesium sulphate 80, sodium phosphate 102, calcium phosphate 162, potassium phosphate 280, calcium lactate 390, iron citrate 35, potassium iodide 0.2. It is the mixture used for the rat colony in this department with the addition of 100 parts of sodium bicarbonate. About 3 mg. of ascorbic acid per rabbit per day were allowed. Sometimes it was given separately, but usually it was mixed up with the diet. There was never any indication that the animals suffered from lack of vitamin C. In order to make the rabbits eat the diet, a few special precautions were taken. The diet was added slowly to the bran, on which they had previously been fed, and the animals were made to "eat clean"—that is the food was weighed out each day and only a sufficiency was given. The food was taken away at night. The rabbits had a good appetite in the morning and most of the food was eaten then.

Three adult male rabbits were used at first. Two of these animals were on this diet for one month. They were perfectly well. One gained weight steadily and went up from 1430 g. to 1685 g.; the other fluctuated and finally fell slightly from 1590 g. to 1535 g. The third rabbit refused to eat the diet and lost weight rapidly for ten days, when it was transferred to a normal diet.

An attempt was then made to make the rabbits vitamin B<sub>1</sub>-deficient. The vitamin was destroyed by autoclaving the marmite at 130° for 20 min. at  $p_{\text{H}}$  9.5. The two rabbits used in the previous experiment and one other were put on this diet. The same precautions to ensure that the diet should be taken were employed. Further, to prevent any sudden appearance of oedema, the fluid intake was controlled. The normal amount of water taken by these animals varied from 50 to 80 ml. per day. They were given 60 ml. twice a day. The rabbits were kept on the vitamin B<sub>1</sub>-deficient diet for 40 days. During this time they were well. All gained in weight from 1680 to 1710 g., 1510 to 1550 g. and 2520 to 2700 g. respectively. The only abnormal sign or symptom noted was polydipsia. The animals nearly always drank up readily their ration of water—which was considerably more than they would normally have taken. They were housed originally in cages with sawdust on the floors. It was thought that either sawdust or coprophagy might be a possible source of vitamin B<sub>1</sub>, although there was no

<sup>1</sup> Kindly supplied by "Transparent Paper Ltd.," Bridge Hall Mill, Bury.

direct evidence. Half-way through the experimental period, they were put in cages with wire floors, but this had no effect on their health.

The survival in health of these rabbits on this diet would suggest the possibility that vitamin B<sub>1</sub> is being synthesised in the alimentary canal. Unfortunately circumstances make it impossible to investigate this point further at the moment, but it is thought that a note of this diet would be useful to others doing any nutritional work on rabbits.

# CCXCV. A NOTE ON THE METHOD OF ESTIMATING VOLATILE ACIDS IN BACTERIAL CULTURES.

BY LESLIE ALFRED ALLEN AND JOHN HARRISON.

*From the Department of Agricultural Bacteriology, University of Reading.*

*(Received September 24th, 1935.)*

INVESTIGATIONS on the estimation of volatile acids, from both theoretical and practical considerations, have been numerous. Most authors have, however, confined their attention to solutions containing only volatile acids and the literature dealing with the influence of interfering substances on the accuracy of results is small. Thus the empirical methods of Duclaux [1900; 1901], the theoretical considerations of Richmond [1907] and Wiegner [1919] and the work of Dyer [1916] apply to pure solutions only and results based upon these methods become decidedly inaccurate when applied to fluids containing a mixture of organic and inorganic substances such as a bacterial culture.

In general the difficulties of estimating volatile acids in bacterial cultures may be summarised as follows.

(1) Other substances present, particularly lactic acid, may partially distil in steam and add to the titration value of the distillate. Carbon dioxide, whether present as such in the culture fluid or produced as a result of partial decomposition of other substances during the distillation, will have a similar though smaller effect.

(2) The acids contained in the culture may be neutralised, either through the presence of chalk added for that purpose before inoculation or through the simultaneous production of ammonia or other bases as a result of bacterial metabolism. In this case it becomes necessary to add a non-volatile acid to liberate the volatile acids and, as the quantity of the latter is unknown, excess of the former must be used, which means that the effect of  $p_H$  and the liberation by the added acid of interfering substances must be considered.

(3) No arbitrary limit can be set to the amount of steam-distillation required to remove all volatile acids since the rapidity with which they are carried over depends on their molecular weight and on the presence of substances, such as soluble salts, which affect their distillation constants. This introduces some difficulty as to knowing when the end-point of distillation is reached.

Foreman and Graham Smith [1928] recommend the steam-distillation of an alcoholic extract previously acidified with hydrochloric acid, and Foreman's method [1928] for eliminating carbon dioxide from this extract minimises errors due to this substance. The use of alcohol, however, greatly increases the bulk of the liquid to be distilled and the method is still subject to many of the difficulties mentioned above. Great accuracy is not in fact claimed, except as regards the method of  $CO_2$  elimination.

Virtanen and Pulkki [1928] recommend for bacterial cultures a preliminary distillation in steam with titration of successive quantities of 200 ml. of distillate, the first fraction being boiled under reflux to remove carbon dioxide. The collected neutralised distillate is then treated with sulphuric acid to liberate volatile

acids and an aliquot portion used for determination of the distillation constant by direct boiling in an apparatus of exact dimensions. No results for actual cultures appear to be given by these authors.

Dyer's method of distilling in steam at constant volume has the advantage that by titrating successive equal quantities of the distillate the end-point may be recognised by the attainment of a small constant titration value after all the volatile acids have been removed. On the other hand the total titration value obtained in this way may represent much more than the volatile acids if there were originally present substances, such as lactic acid, which partially distil. To eliminate this error it is therefore necessary to collect all the fractions of the first distillate and submit them to a second steam-distillation when, as pointed out by Virtanen and Pulkki, the concentration of the lactic acid is so small as to be negligible.

For these reasons the following method was evolved and was found to give satisfactory results:

A suitable quantity of the original culture (100–150 ml.) was acidified with excess of strong sulphuric acid and steam-distilled at constant volume. This was attained by marking the level of the liquid in the distillation flask and heating the latter by a suitably adjusted burner at the same time as a current of steam was passed through the liquid. The distillate was passed through a Liebig's condenser and collected in successive fractions of 100 ml. in measuring cylinders. These fractions were titrated with standard baryta to phenolphthalein and the distillation discontinued when a small constant value was obtained. The successive neutralised fractions were combined, evaporated to a small volume (70–80 ml.), transferred to a flask and the volatile acids liberated by the addition of a quantity of *N* sulphuric acid equivalent to the total amount of baryta used during titration. After shaking thoroughly the flask was left overnight to allow the barium sulphate to settle. The latter was removed by filtration, the precipitate washed and the filtrate made up to a convenient volume (*e.g.* 100 ml.). Carbon dioxide was removed by boiling for 10 min. under a reflux condenser and the liquid again distilled in steam at constant volume, successive portions of the distillate being titrated as before and the process discontinued when a small constant value was attained. The volatile acids were then represented by the total titration value but it was necessary to apply a small correction by subtracting the final small constant value from the titration figure for each 100 ml. fraction of the distillate.

To determine the nature of the volatile acids when required it was found satisfactory to collect and evaporate the neutralised fractions of the second distillation, liberate the volatile acids by the addition of the correct quantity of *N* sulphuric acid, make up the volume of the filtered liquid to 110 ml. and apply Duclaux's methods. Alternatively, the collected fractions of the second distillation could be used for the application of Dyer's method, the liberated acids being steam-distilled from a constant volume of 150 ml.

The following examples will make the method clear and indicate its usefulness in the elimination of errors:

*Exp. 1. Value given by fresh medium acidified with  $H_2SO_4$ .* In order to find the value given by a fresh medium containing protein and carbohydrate, but no volatile acid, a medium containing 1% peptone, 5% dextrose and 0.3% yeast extract was prepared. To 100 ml. of this were added 5 ml. of strong sulphuric acid and the volume made up to 150 ml. with water. The duplicate titration values for the first and second distillations are shown in Table I together with the final corrected values for "volatile acids".

Table I. "*Volatile acid*" value given by fresh medium acidified with  $H_2SO_4$ .

Titration values in ml. of 0.1196 N baryta

Distillate ml.	First distillation duplicates		Second distillation duplicates	
	I	II	I	II
100	0.34	0.30	0.30	0.28
200	0.35	0.61	0.23	0.20
300	0.35	0.21	0.19	0.16
400	0.25	0.34	0.15	0.14
500	0.20	0.36	0.10	0.10
600	0.19	0.21	0.11	0.07
700	0.20	0.17	0.06	0.06
800	0.21	0.20	0.07	0.06
900	0.21	0.22	—	—
1000	0.28	0.23	—	—
Total	2.58	2.85	1.21	1.07

Corrected values (for second distillation) converted into  $N/10$ :

I.  $\{1.21 - (8 \times 0.06)\}$   $1.196 = 0.87$ .

II.  $\{1.07 - (8 \times 0.06)\}$   $1.196 = 0.71$ .

*Exp. 2. Influence of lactic acid.* The influence of lactic acid in raising the titration value of the distillate and its elimination by the second distillation were shown by adding to the same medium as above 20 ml. of 20% lactic acid, making up the volume to 150 ml. and distilling as previously. Results are given in Table II. It will be seen that a concentration of rather less than 3% of lactic acid in the liquid being distilled adds considerably to the titration value of the distillate but that a second distillation eliminates most of the error.

Table II. *Influence of lactic acid.*

100 ml. of medium, 20 ml. 20% lactic acid + 30 ml. water.

Titration values in ml. of 0.1196 N baryta

Distillate ml.	First distillation duplicates		Second distillation duplicates	
	I	II	I	II
100	1.30	1.48	0.68	0.50
200	1.24	1.29	0.40	0.33
300	1.14	1.17	0.30	0.24
400	0.97	1.10	0.22	0.17
500	1.05	1.13	0.13	0.15

1000	1.04	1.09	0.06	0.06
1100	0.98	1.05	—	—
Total	11.61	12.77	2.12	1.78

Corrected values (for second distillation) converted into  $N/10$ :

I.  $\{2.12 - (10 \times 0.06)\}$   $1.196 = 1.82$  ml.

II.  $\{1.78 - (10 \times 0.06)\}$   $1.196 = 1.41$  ml.

*Exp. 3. Determination of acetic acid in presence of lactic acid.* To test the efficiency of the method in determining a volatile acid in the presence of lactic acid the same fresh medium was used and to this were added 20 ml. of 20%

lactic acid and 5 ml. of acetic acid of known strength. Table III shows the results obtained by the same procedure as before. It will be seen that there is good agreement between the duplicates in the second distillation and between these values and the quantity of acetic acid originally added, showing that errors due to the presence of lactic acid and other factors have been eliminated and that the "yield" of volatile acid is very good.

Table III. *Determination of acetic acid in presence of lactic acid.*

100 ml. of medium, 20 ml. 20% lactic acid, 5 ml. acetic acid, 25 ml. water.

Distillate ml.	Titration values in ml. of 0.1196 <i>N</i> baryta			
	First distillation duplicates		Second distillation duplicates	
	I	II	I	II
100	30.80	26.47	24.59	28.54
200	18.30	18.00	15.81	17.58
300	11.23	11.84	10.52	10.03
400	7.48	7.93	6.80	5.89
500	5.26	6.19	4.55	3.79
600	3.65	4.63	3.24	2.57
700	2.71	3.54	2.23	1.69
800	1.75	2.68	1.62	1.20
900	1.34	2.05	1.20	0.66
1000	1.60	1.62	0.89	0.42
1100	1.35	1.45	0.64	0.32
1200	1.42	1.42	0.41	0.23
1300	—	—	0.30	0.17
1400	—	—	0.22	0.10
1500	—	—	0.15	0.06
1600	—	—	0.09	0.05
1700	—	—	0.05	0.07
1800	—	—	0.06	—
Total	86.89	87.82	73.37	73.37

Corrected values (for second distillation) converted into *N*/10:

I.  $\{73.37 - (18 \times 0.06)\} 1.196 = 86.46$  ml.

II.  $\{73.37 - (17 \times 0.06)\} 1.196 = 86.53$  ml.

Amount of *N*/10 acetic acid added = 86.56 ml.

On the other hand it must be borne in mind that "blank" determinations on the same medium *plus* lactic acid, but without any acetic acid, produced figures of 1.82 and 1.41 (Table II)—an average of 1.61. Theoretically, then, the estimations shown in Table III should have given the true value of acetic acid (86.56) plus the figure due to the medium and lactic acid alone (1.61)—or a total figure of 88.17. The explanation of the lower figure obtained in practice may be either (1) that in the presence of appreciable volatile acid the lactic acid shows less tendency to steam-distillation, or (2) that there has been a slight loss of volatile acid sufficient to balance the effect of the lactic acid in increasing the titration figure of the distillate. It should, moreover, be realised that in dealing with a bacterial culture, for which the methods described here are chiefly intended, it is impossible to make a "blank" determination, so that the calculation of results must be made on the assumption that a double distillation removes most of the error due to interfering substances (see calculation of results at foot of Table IV). The results in Table II show that in any case the final error due to this cause is small and the figures in Table III indicate that, when appreciable quantities of volatile acids are present, the error is likely to be still further reduced.

*Exp. 4. Determination of volatile acids in a bacterial culture.* The ability of the method to give satisfactory duplicates when used for a bacterial culture was tested as follows:

Two separate quantities of 500 ml. of a sterile medium containing 1% peptone, 5% dextrose and 0.3% yeast extract, with 25 g. of added chalk, were inoculated with two different strains of lactobacilli isolated from silage and incubated at 30° for several weeks, the cultures being well shaken each day to facilitate neutralisation of the metabolic acids by the chalk. The residue of chalk was then removed by filtration and washed, the volume of filtrate being made

Table IV. *Estimation of volatile acids in a culture of Lactobacillus (Strain 1).*

Distillate ml.	Titration values in ml. of 0.1300N baryta

1100	1.00	0.90	0.15	0.14
Total	32.16	31.75	23.83	23.41

Corrected values (for second distillation) converted into N/10:

I.  $\{23.83 - (11 \times 0.15)\}$  1.196 = 26.53 ml.

II.  $\{23.41 - (11 \times 0.14)\}$  1.196 = 26.16 ml.

up to 500 ml. Duplicate determinations on each culture were made by adding to 75 ml. of the filtrate 5 ml. of strong sulphuric acid, to liberate the organic acids, and 20 ml. of water and distilling as before. Results are shown in Tables IV and V. Tests of the cultures for other metabolic products showed that Strain 1 produced 1.26% of lactic acid and no other product except acetic acid, whilst strain 2 produced 0.39% of lactic acid, 0.3% of alcohol and the volatile acids were a mixture of acetic and butyric. Table IV shows that the titration values of the first distillate are much higher than those of the second distillate, while in Table V the discrepancy is not nearly so great. This is in agreement with the fact that strain 1 produced a much higher percentage of lactic acid. The agreement between the duplicates in the second distillation is, in the case of both strains, reasonably good. Table IV shows particularly well the errors inherent in a method relying on a primary distillation only.

#### SUMMARY.

Details are given of a method of estimating volatile acids in bacterial cultures which eliminates most of the errors due to the presence of lactic acid, carbon dioxide and other interfering factors. It has been shown that the "yield" of volatile acid by this method is high and that reasonable consistency between duplicates can readily be obtained.

The authors wish to express their thanks to the Research Council of Imperial Chemical Industries Limited for a grant in aid of this research.

# CCXCVI. CRESS SEED MUCILAGE.

By KENNETH BAILEY.<sup>1</sup>

*From the Biochemical Department, Imperial College of Science  
and Technology, South Kensington.*

*(Received September 26th, 1935.)*

THE dispersed cellulose component which is found in white mustard seed mucilage [Bailey and Norris, 1932] and in quince seed mucilage [Schmidt, 1844; Kirchner and Tollens, 1874; Renfrew and Cretcher, 1932] has now been obtained from the mucilage of cress seed, *Lepidium sativum*. The present communication, which deals mainly with the chemistry of this seed mucilage, falls into three sections. (1) the products obtained by acid hydrolysis of cress seed mucilage are characterised; (2) the mucilage is shown to be a heterogeneous polysaccharide system, and its behaviour towards fractionating agents is contrasted and compared with those of the closely related mucilage of white mustard seed and the non-cellulosic mucilage of linseed; (3) the factors responsible for the hydration and dispersion of the cellulose component in seed mucilages and in other cellulose polyuronide systems are discussed.

Since the earlier review of Bailey and Norris [1932] several contributions to the chemistry of the mucilages have been made, chiefly by American workers in this field. *d*-Galactose, *l*-rhamnose and galacturonic acid have been found in the hydrolytic products of the mucilage of slippery elm bark [Anderson, 1934]. The uronic acid is combined in part as a rhamnosegalacturonide, an aldobionic acid found previously by Anderson and Crowder [1930] in the hydrolysis products of linseed mucilage. The latter mucilage has now been shown to contain the *l*-form of galactose [Anderson, 1933] and the *d*-form of galacturonic acid [Niemann and Link, 1934]. The frequent occurrence of structurally related carbohydrates, *i.e.* of *d*-galactose, *d*-galacturonic acid with *l*-arabinose, and of *d*-glucose, *d*-glycuronic acid with *d*-xylose, has given considerable support to the classical hypothesis of de Chalmot [1894, 1, 2], who first suggested that pentosan may arise from hexosan by a two-stage process: oxidation of the hexose to the uronic acid followed by decarboxylation to the pentose. The occurrence of *l*-galactose with *d*-galacturonic acid in linseed mucilage is therefore an interesting anomaly. The mucilage of *Psyllium* seed, investigated by Anderson and Fireman [1935] consisted of a mixture of polyuronides, which were hydrolysed to *d*-galacturonic acid, *l*-arabinose and *d*-xylose. This latter sugar has also been isolated from *Psyllium* seed mucilage by the present author. Quince seed mucilage on hydrolysis yields *d*-xylose, *l*-arabinose and a mixture of monomethylated and unmethylated pentoseuronic acid [Renfrew and Cretcher, 1932]. The ultimate constituents of white mustard seed mucilage are arabinose, rhamnose, galactose, galacturonic and glycuronic acids [Bailey and Norris, 1932].

## EXPERIMENTAL.

### *Preparation of cress and other seed mucilages.*

When cress seed is allowed to soak in water the mucilaginous layer of the seed testa swells but does not disperse and cannot be squeezed away, as in the case of mustard seed mucilage. The difficulty was overcome in the following

<sup>1</sup> Beit Scientific Research Fellow.

way. 200 g. of seed were washed free of extraneous matter, mixed with 2 litres of distilled water and shaken mechanically in a Winchester bottle for 6 hours. The mucilage, gradually dispersed by the friction of the vessel walls and of seed against seed, constituted the topmost layer on centrifuging. The seed residues were treated once more in a similar way and then discarded. The mucilage was squeezed through muslin to remove seed fragments, poured into 95 % alcohol, dehydrated in absolute alcohol and finally dried *in vacuo* at room temperature. To reduce the high ash content (usually 6–7 %), the snow-white fibre was redispersed in water, 12 % HCl was added to a final concentration of 2 %, and the mucilage reprecipitated with 95 % alcohol. The product was then pressed free of excess liquor, washed with alcohol until free from acid and dried as before. The yield of mucilage was 2.6 % of the weight of the original seed.

In the preparation of both linseed and white mustard seed mucilages prolonged agitation of the seed was unnecessary and the mucilage was separated by pouring on to a Büchner filter, the perforations of which were sufficiently small to prevent the passage of the seed.

#### *Methods of analysis.*

The methods of analysis adopted throughout may conveniently be described here. Furfuraldehyde yields were determined by the standard Krüger-Tollens-Kröber method [Van der Haar, 1920; Browne, 1912]. The conversion of furfuraldehyde figures into terms of pentosan has been purposely avoided, since this procedure has been criticised by several authors in recent times [*e.g.* the critique of Peter *et al.*, 1933]. Even if the Kröber tables for such a conversion are substantially correct, it is essential to ascertain in the case of polyuronic material the proportion of furfuraldehyde arising from pentosan and uronic acids respectively. It has been erroneously assumed in the past that uronic anhydride groups gave one-sixth their weight of furfuraldehyde. Ehrlich and Schubert [1929], using pure *D*-galacturonic acid monohydrate, found that 2.64 parts of acid gave one part of furfuraldehydophloroglucide; *i.e.* 1 part of uronic anhydride yields 22.7 % of furfuraldehyde. These values have been confirmed by Norris and Resch [1935]. Since the amount of uronic anhydride in any material can be ascertained by the method of Lefèvre [1907] and subsequent modifications (*e.g.* those of Nanji *et al.*, 1925; Dickson *et al.*, 1930) it is now possible to calculate more accurately than hitherto the amount of furfuraldehyde which arises from pentose by making due allowance for the furfuraldehyde yield of the uronic anhydride.

The determination of methylpentosan in presence of other furfuraldehyde-yielding products appears to be wholly inaccurate. The original method proposed by Ellett and Tollens [1905] makes use of the fact that methylpentoses give rise on distillation with HCl to methylfurfuraldehyde, which unlike furfuraldehyde forms an alcohol-soluble phloroglucide. With material obtained from plant sources the alcoholic extract invariably contains  $\omega$ -hydroxymethylfurfuraldehyde which arises in varying amounts from hexosan. The interpretation of alcohol-soluble phloroglucide material in terms of methylpentose becomes in consequence a doubtful procedure. Experience shows, moreover, that in duplicate experiments the amounts of alcohol-soluble phloroglucide are not concordant unless the rates of distillation are rigidly standardised, though small variations do not affect the absolute furfuraldehyde yield. The presence of methylfurfuraldehyde can at least be detected qualitatively by the reddish brown colour of the alcoholic extract, and products which contain no rhamnose, *e.g.* the Cross and Bevan cellulose fractions of the mucilages investigated, give

only a pale green phloroglucide extract. With these considerations in mind it has been thought advisable to record merely the amount of alcohol-soluble phloroglucides expressed as a percentage of the original material and to infer the presence or absence of methylpentose from the colour of the alcoholic extract.

Reducing groups were estimated by the Willstätter and Schudel hypiodite method [1918], care being taken to obtain conditions of quantitative oxidation as outlined by Bailey and Hopkins [1933]. Cellulose determinations were carried out by the Cross and Bevan [1899] method, nitrogen determinations by the micro-Kjeldahl method and methoxy-groups by a modification of the Zeisel method.

*Acid hydrolysis of cress seed mucilage.*

A typical analysis of cress seed mucilage gave: ash 1.0%, uronic anhydride 25.8%, furfuraldehyde 24.5%, alcohol-soluble phloroglucides 2.86%, Cross and Bevan cellulose 18.3%, methoxyl 1.4%, nitrogen 0.1%.

In general the material was hydrolysed under standard conditions with dilute sulphuric acid, which was then removed by addition of barium carbonate with rapid mechanical stirring. After filtration, the clear liquid was evaporated *in vacuo* at 50°, filtered and poured into 95% ethyl or methyl alcohol. The flocculum of barium salts was centrifuged off, washed with 95% alcohol, redissolved in water, reprecipitated with methyl alcohol, once more dissolved and reprecipitated and finally filtered yielding a compact mass of barium salts. These were washed with absolute methyl alcohol and dried *in vacuo* over  $P_2O_5$ , first at room temperature and finally at 70°. The alcoholic solution containing the sugars was evaporated to a small bulk *in vacuo* and thinned with methyl alcohol to remove a small amount of barium salt, which was separated from the sugar solution by centrifuging. The resulting barium-free solution was reserved for fractionation and crystallisation.

36 g. of mucilage (ash- and moisture-free basis) were hydrolysed at 80° for 20 hours in 1 litre of 2% sulphuric acid. After separation of the cellulose residue (*A*) the hydrolysate was treated in the manner described above and gave rise to a sugar fraction (*B*) and the barium salt (*C*). On drying (*C*) weighed 11 g. and contained 15.1% of barium and 40.0% of uronic anhydride, values which do not quite satisfy the requirements of a product composed solely of one or of several aldobionic nuclei. The salt was therefore decomposed with the calculated amount of sulphuric acid and subjected to further hydrolysis with 2% acid at 97° for 6 hours. From the hydrolysis products were isolated 8 g. of barium salt (*D*) and a sugar fraction (*E*). The cellulose residue (*A*) was further hydrolysed under the same conditions as barium salt (*C*) and the final residue (*F*) was freed from acid by washing in water, dehydrated in boiling alcohol and finally dried at 105°.

*Characterisation of the hydrolysis products.*

*Sugar fractions.* Fraction (*B*) was evaporated to dryness and extracted with 750 ml. of boiling absolute alcohol in 50 ml. portions. The united extracts were concentrated to a syrup, thinned with 90% alcohol and left in the ice-chest to crystallise. The separated material was filtered on a coarse sintered glass filter, washed with absolute alcohol and ether and dried *in vacuo* at 70° over  $P_2O_5$ . It weighed 1.1 g. and proved to be *l*-arabinose:  $[\alpha]_D^{25} + 103^\circ$  ( $c=1.8$ ). The diphenylhydrazone and *asmethylphenylhydrazone* separated from alcoholic solution in the cold and after two recrystallisations from dilute alcohol melted at 204° and 164.5° respectively.

The sugar fraction (*E*) together with the mother-liquor remaining after crystallisation of the arabinose from fraction (*B*) were combined and gave 1.1 g. of galactose *α*-methylphenylhydrazone when treated by the procedure of Van der Haar [1920]. The hydrazone was decomposed by formaldehyde by Van der Haar's modification of earlier methods. The final syrup readily crystallised, and the sugar, isolated by the method given above, weighed 0.2 g. and proved to be *D*-galactose:  $[\alpha]_D^{20} + 81.7$  ( $c = 1.2$ ). On oxidation with nitric acid (sp. gr. 1.12), mucic acid was obtained, M.P. 220°.

*D*-Glucose from the cellulose residue (*F*). The residue on analysis gave: ash 2.5%, uronic anhydride 1.8%, furfuraldehyde 6.7%. 2.5 g. were hydrolysed with cold 72% sulphuric acid according to the method of Monier-Williams [1921]. Of the original residue 0.21 g. remained insoluble. The amount of sugar recovered, estimated as glucose by the hypiodite method, was 90% of the theoretical, and the specific rotation, also calculated on this basis, was  $[\alpha]_D^{20} + 40.1^\circ$ . The aqueous sugar solution was evaporated *in vacuo* and alcohol was added to a concentration of 75%. On standing 0.97 g. of crystalline glucose,  $[\alpha]_D^{20} + 50^\circ$  ( $c = 1.5$ ), was obtained. The phenylosazone prepared both from the mother-liquor and the sugar had the characteristics of glucosazone, and after several recrystallisations from dilute alcohol melted at 205°. Specific tests for arabinose were negative, although some pentose was present.

*Barium salt (D)*. After reprecipitating twice from methyl alcohol, the dried salt weighed 8.5 g. and gave on analysis; barium 16.9%, uronic anhydride 41.5%, methoxyl 2.4%, furfuraldehyde 10.4%, alcohol-soluble phloroglucides 11.8%, —CHO 3.96%, nitrogen 0.009%;  $[\alpha]_D^{20} + 89^\circ$  ( $c = 5.8$ ). Except for the low reducing power, the analytical figures would indicate that salt (*D*) consists of a mixture of methylpentose barium uronide and hexose barium uronide. The —CHO content of the former is 7.1%, of the latter 6.85%. The salt in question, with a value of 3.96%, approximates more closely to a molecule which could arise by linkage of two aldobionic acids. This preliminary supposition as to the nature of salt (*D*) is borne out by later experiments. Since, however, the salt gives on hydrolysis rhamnose and galactose two possibilities arise: (1) that these sugars, linked to galacturonic acid, form part of the same skeletal molecule; (2) that each sugar is a component of distinct skeletal molecules. For purposes of analytical comparison it is more convenient to represent salt (*D*) under the first category. The results quoted above are therefore recalculated on a methoxy-free basis, and compared with the calculated values for the barium salt of an acid produced by linking galactose barium uronide with rhamnose barium uronide.

	Found %	Calculated for $C_{21}H_{36}O_{22}Ba$ %
Barium	17.1	16.85
Uronic anhydride	42.0	43.3
Furfuraldehyde	10.5	9.8*
Alcohol-soluble phloroglucides	11.9	—
—CHO	4.0	3.6
C	35.0	35.4
H	4.97	4.43

\* Calculated by the factor of Ehrlich and Schubert [1929].

*Oxidation of the barium salt (D)*. 0.5 g. was simultaneously hydrolysed and oxidised in presence of 7% HBr and bromine by the method of Heidelberger and Goebel [1927]. 0.05 g. of purified mucic acid, M.P. 220°, was obtained, derived solely by oxidation of galacturonic acid and not of galactose.

1.62 g. were oxidised by barium hypoiodite, following closely the method of Goebel [1927]. The free carbonyl group was thus oxidised to carboxyl, and the fully oxidised acid was isolated as the barium salt which contained, after one precipitation from methyl alcohol, 23.0 % of barium, a value which remained unchanged after two further precipitations. On analysis the final product gave: barium 23.0 %, furfuraldehyde 8.6 %, alcohol-soluble phloroglucides 8.0 %, methoxyl 0.6 %,  $-\text{CHO}$  0.6 %; calculated barium content 22.9 %. By way of comparison, the barium salt of an oxidised hexoseuronic acid is 27.0 % and of an oxidised methylpentoseuronic acid 27.9 %. If a correction be made for the increase in molecular weight which occurs on oxidation, the furfuraldehyde yield of the oxidised salt is 9.5 %, and of the alcohol-soluble phloroglucides 8.8 %, corresponding to the values 10.4 % and 11.9 % in the case of the original salt. Since furfuraldehyde arises solely from uronic acid, and alcohol-soluble phloroglucides from rhamnose, the figures indicate that no appreciable oxidation of these two components has occurred.

*Hydrolysis of salt (D).* 8 g. of the salt after precipitation of the barium were hydrolysed for 16 hours with 2.5 % sulphuric acid in an oil-bath at 105°, and after appropriate treatment gave a syrupy sugar fraction (*G*) and a barium salt (*H*). The former was dissolved in water, cleared with norite, evaporated to a thin syrup and allowed to crystallise in the ice-chest. Crystals of *l*-rhamnose monohydrate appeared after 2 days and were filtered off after standing for a week. They were washed rapidly with dilute alcohol and dried on a porous plate. They weighed 0.36 g. and melted at 94°:  $[\alpha]_D^{20}$ , calculated for the anhydrous form, +9.2° ( $c=1.5$ ). The *p*-bromophenylosazone melted at 218° and the phenylosazone at 181°. A portion of the mother-liquor after crystallisation of rhamnose was treated with *o*-methylphenylhydrazine in alcoholic solution. A copious precipitate of the galactosehydrazine separated on standing overnight in the cold and after two recrystallisations from alcohol melted at 189°. Another portion of the mother-liquor was oxidised with nitric acid and gave a precipitate of mucic acid, melting after purification at 220°. No other sugars could be detected.

The barium salt (*H*) after purification weighed 2 g. and contained 26.7 % of barium (calculated for barium galacturonate, 26.2 %). 1.74 g. were decomposed with the calculated amount of *N*/10 sulphuric acid, and the aqueous solution after filtration was evaporated *in vacuo* at 35°, taken up in alcohol and again evaporated to a thick syrup, which crystallised on standing for several days in a desiccator. The crystals of  $\beta$ -*D*-galacturonic acid were filtered off, washed with absolute alcohol and dried on a porous plate over sulphuric acid. The acid turned brown at 158° and decomposed at 166°:  $[\alpha]_D^{20}$ , at 11 min., +40°; at constant rotation, +55.4° ( $c=1.2$ ). On titration against standard NaOH, using phenolphthalein as indicator, 12.10 mg. acid required 3.10 ml. of *N*/50 NaOH; calculated, 3.14 ml. The  $-\text{CHO}$  content, determined by the hypoiodite method was 13.8 %; calculated 14.9 %. 0.14 g. oxidised by bromine water at room temperature for a week gave 0.06 g. of mucic acid, m.p. 220°. With Schiff's reagent the acid gave a colour only after long standing. The  $\beta$ -*D*-galacturonic acid isolated by Ehrlich and Schubert [1929] had the following constants: m.p. 160°,  $[\alpha]_D^{20}$ , at 1 min., +27°, at 24 hours +55.3°.  $\alpha$ -*D*-Galacturonic acid monohydrate has the same final rotation as the  $\beta$ -form, but exhibits a downward mutarotation. The two forms are readily interconvertible.

*Constitution of the salt (D).* The experimental data leave the exact constitution of the salt an open question. After oxidation by hypoiodite the methylfurfuraldehyde and furfuraldehyde yields indicate that the rhamnose and uronic acid components are not appreciably affected and that in consequence the free

aldehyde group belongs to the remaining component, galactose. If this be the case, the galactose moiety occupies a terminal position in the skeletal molecule. These conclusions, based merely on furfuraldehyde and methylfurfuraldehyde yields, would indicate that the salt is a homogeneous product representable by the formula already given, but on such data alone it is perhaps unwise to stress the homogeneity of the salt since the mucilage itself is an essentially heterogeneous system. The experimental data considered *in toto* however do conform with the view that the hydrolysis has been arrested at a stage in which two molecules of galacturonic acid are linked to two sugar molecules.

*Fractionation of cress and other seed mucilages.*

Bailey and Norris [1932] showed that white mustard seed mucilage could be separated into at least three components by fractionation methods involving the use of cold baryta and hot sodium hydroxide solution. In the following experiments the cellulose-containing mucilages of cress and white mustard seed and the non-cellulosic mucilage of linseed have been subjected to the action of baryta in the cold and of boiling 1 % NaOH; in two cases fractional precipitation by alcohol has been achieved.

*Fractionation by means of baryta.* 10 g. of mustard seed mucilage, 10 g. of cress seed mucilage and 40 g. of linseed mucilage (on an ash- and moisture-free basis) were used. The mucilage was dispersed in 100 parts of water and an equal volume of saturated baryta was added, CO<sub>2</sub> being rigidly excluded. After mixing and allowing to stand overnight the supernatant liquor was separated from the baryta-insoluble residue by decantation or by centrifuging. The residue was squeezed free of excess liquor in muslin, redispersed in water and made neutral by addition of HCl; more acid was added to a concentration of 2 %, and complete precipitation was effected by pouring into 95 % alcohol. The resulting product was freed from acid by repeated washings with absolute alcohol and dried first *in vacuo* at room temperature and then at 105° to constant weight.

*Fractionation by means of sodium hydroxide.* The procedure was incorporated in the general method for the preparation of Cross and Bevan cellulose, whereby polyuronide material was removed by a preliminary boiling with 1 % NaOH for 30 min.

The analysis of each fraction is given in Table I. In the case of the baryta-insoluble residues the ash consisted almost entirely of barium carbonate, and the barium content only is recorded. The extent of partition of pentosan between the various fractions can be ascertained from the column which records the amount of furfuraldehyde arising solely from pentosan. Attention may be drawn to the following points: (1) the extent of solvation of each mucilage in cold baryta is deduced from the experimental yield of insoluble residue and can also be calculated from the amounts of Cross and Bevan cellulose in both products. The baryta-soluble portion amounts to 32 % for mustard seed mucilage, 35 % for cress seed mucilage and 84 % for linseed mucilage; (2) in general, the baryta-insoluble residues, in comparison with the original mucilage, contain the same amount of pentosan, less methylpentosan and less uronic anhydride, except in the case of the linseed residue in which the uronic anhydride content reaches 41 %; (3) the mucilages incompletely precipitated by alcohol contain less uronide and less pentosan than those completely precipitated; (4) the Cross and Bevan cellulose residue of mustard seed contains 5 % uronic anhydride and a trace of pentosan, whilst that from cress mucilage contains 2 % of uronic anhydride but yields 20 % of furfuraldehyde, a figure which is reduced to about 7 % if the cellulose is prepared by mild acid hydrolysis of the mucilage. The cellulosic

residue of linseed amounts only to 0.5%, and was not investigated; (5) the nitrogen content, which exceeds 0.3%, only in two cases, probably arises from protein impurities. The methoxyl groups persist through the fractionation process.

From these results it is clear that the three mucilages investigated are systems of mixed polyuronides. Those components containing most uronic acid groups are dissolved, as one would expect, by dilute baryta, whilst complete or almost complete solution of the polyuramide is effected by boiling with 1% NaOH. Cautious addition of alcohol to the aqueous dispersate of the mucilage precipitates fractions poor in uronic acid. It is probable that a more rigorous fractionation by alkali and/or alcohol would permit the preparation of homogeneous fractions, but this has not yet been attempted.

#### *Dispersibility of cellulose polyuramide systems.*

The complexity of seed mucilages is illustrated not only by the variety of ultimate hydrolysis products but also by their amenity to methods of fractionation, and it is of great interest to consider how the dispersion of a cellulose component in such a heterogeneous system can arise. Firstly it must be borne in mind that the polysaccharide chains of the cellulose-containing mucilages are definitely oriented and are precipitated by alcohol from their aqueous dispersates in the form of short fibres. These are best obtained from mustard seed mucilage, which has a high cellulose content, and the fibrous form indicates that the polysaccharide chains are oriented parallel or approximately parallel with each other and with the fibre axis. Although the polyuramide chains may not penetrate the cellulose micelle they must at least surround it and since they are of comparatively low molecular weight they must also reduce the lateral intermicellar

forces between such micelles. Of these forces little is known, but in the case of normal cotton fibre they are sufficiently large to prevent dispersion. On immersion in water, the polyuronide chains, containing ionisable carboxyl groups, become hydrated and swell, and the cellulose micelles become dispersed. These latter may themselves become hydrated since their affinity for water molecules will be enhanced if some of the hexose molecules are oxidised to uronic acid. This appears probable in the case of mustard seed mucilage, in which some uronic groups resist alkaline leaching. Furthermore, if the individual skeletal chains of the cellulose component are shorter than those of normal cotton fibre, the secondary valency or Van der Waal forces between neighbouring chains will not be so large and will facilitate the entry of water molecules.

In the dispersed condition, therefore, the mucilage consists of a network of hydrated cellulose micelles, interspersed with the more heavily hydrated uronide chains. The extent of dispersion will depend ultimately on the size of the cellulose micelle, the chain length and the proportion of hydrated (as distinct from dissolved) polyuronides. When these latter are completely dissolved by alkali, the cellulose micelles are drawn together and a visible separation of the cellulose component occurs. When, on the other hand, dilute acid is added to the aqueous mucilage dispersate, no separation occurs until the polyuronides are hydrolysed by heating, and the cellulose component then appears in a gel-like condition and can be obtained in fibrous form by squeezing in muslin. Some of the polyuronides in aqueous dispersates of cress seed mucilage are already dissolved and can be precipitated by alcohol from the clear aqueous layer which separates on high speed centrifuging.

The importance of the factors responsible for the hydration and dispersion of cellulose polyuronide systems is not confined to the products examined here. The cell wall itself is essentially heterogeneous, consisting in the simplest cases of a cellulose matrix in close association with polyuronide (*i.e.* pectin and hemicellulose) material. In the walls of the meristematic tissue of the shoot apex it has been observed that the pectin-cellulose complex is heavily hydrated and allows of rapid diffusion of soluble substances [Tupper-Carey and Priestley, 1923]. Clearly, if cellulose and polyuronide chains are laid down simultaneously, the physical condition (hydration, colloidal state *etc.*) of the whole system will be influenced by the exact structural arrangements of its components. In the present state of cell wall chemistry it is impossible to compare the cell wall system with the cellulose-containing mucilages, since it is essential to ascertain the orientation and distribution of the polyuronides in the cell wall. The pectin for instance may occupy a regional position, as in the middle lamella, may be distributed uniformly or may alternate with the cellulose in well defined layers, a structure which has been assigned by Anderson [1927] to the collenchyma cells of flax bast fibres. A more detailed discussion of these problems will be found in recent papers by Seifriz [1934] and Buston [1935]. It is sufficient to emphasise here that the colloidal condition of the cell wall, before deposition of fat and lignin, is intimately related to the molecular architecture of the cellulose and polyuronide components.

#### SUMMARY.

1. Cress seed mucilage, like white mustard and quince seed mucilages, contains a dispersible cellulose component and gives rise on acid hydrolysis to *l*-arabinose, *d*-galactose, *l*-rhamnose, *d*-glucose (from the cellulose component) and *d*-galacturonic acid, all of which have been isolated in crystalline forms. At a given stage in the hydrolysis the uronic acid is obtained in a fragment formed

probably by linkage of two aldobionic acids. The barium salt of the uronide present at this stage thus conforms analytically, except for the reducing power, to the requirements of a barium aldobionate. From the hydrolytic products of the salt were isolated  $\beta$ -*D*-galacturonic acid, *l*-rhamnose monohydrate and the *as*-methylphenylhydrazone of galactose. Whether the two sugars constitute part of one or of separate units is an open question.

2. The two cellulose-containing mucilages of white mustard seed and the non-cellulosic mucilage of linseed are found to be heterogeneous polysaccharide systems which lend themselves to methods of fractionation.

3. The factors responsible for the hydration and dispersion of the cellulose component in seed mucilages and other cellulose polyuronide systems are discussed.

I am indebted to Prof. A. C. Chibnall, Dr H. W. Buston and Dr F. W. Norris for their interest and helpful advice.

# CCXCVII. THE KINETICS OF ALCOHOLIC FERMENTATION OF SUGARS BY BREWER'S YEAST.

## III. THE TEMPERATURE COEFFICIENTS OF THE RATES OF FERMENTATION OF GLUCOSE AND FRUCTOSE.

By REGINALD HAYDN HOPKINS AND  
RICHARD HENRY ROBERTS.

*From the Department of Industrial Fermentation, University of Birmingham.*

*(Received September 28th, 1935.)*

THE temperature coefficient of the rate of fermentation by living yeast was investigated by Slator [1908]. His results refer to the reaction which limits that fairly uniform rate which is observed over a wide range of sugar concentration from 1 to 10% in the case of glucose and from 2 to 10% in the case of fructose. These uniform rates and their temperature coefficients were approximately the same for the two sugars. However, the marked difference between the rates of fermentation of the two sugars when the concentrations are low, below 1%, and the phenomenon of selective fermentation of the mixed sugars give rise to the idea that other factors supervene at low concentrations. There are reasons for anticipating an abnormal temperature coefficient in the case of fructose, particularly. The change in optical rotation of solutions of this sugar with change in temperature is usually attributed to a change in the dynamic equilibrium of the various forms of the sugar which are supposed to be present in solution at equilibrium. If we suppose only one (or some) of these components to be specifically fermentable, three cases can arise when a sufficiently dilute solution is fermented, i.e. when the concentration of the fermentable component can influence the rate of fermentation. Firstly the fermentable component may increase with rise in temperature at the expense of the unfermentable one; in this case the observed temperature coefficient will be abnormally high. Secondly the fermentable component may decrease with rise in temperature and an abnormally low temperature coefficient be observed. Thirdly, despite changes in the dynamic equilibrium, the fermentable component itself may not change in concentration with rise in temperature, in which case the temperature coefficient should be normal and the same as at higher concentrations of fructose where the concentration has no appreciable effect on the rate of fermentation. These considerations do not apply in the case of glucose, so that a comparison between the behaviours of the two sugars, glucose being provisionally regarded as a standard, should enable us to decide between the three possible cases discussed above.

### EXPERIMENTAL.

The technique employed was exactly as described by Hopkins and Roberts [1935]. For each concentration of sugar, the observations at all temperatures were made with the same stock of yeast on the same day. The figures given in

the table below are the ratio, velocity of fermentation at  $t+5^\circ$ : velocity of fermentation at  $t^\circ$ . They are represented graphically in Fig. 1, as ordinates, plotted against  $t$  as abscissae.

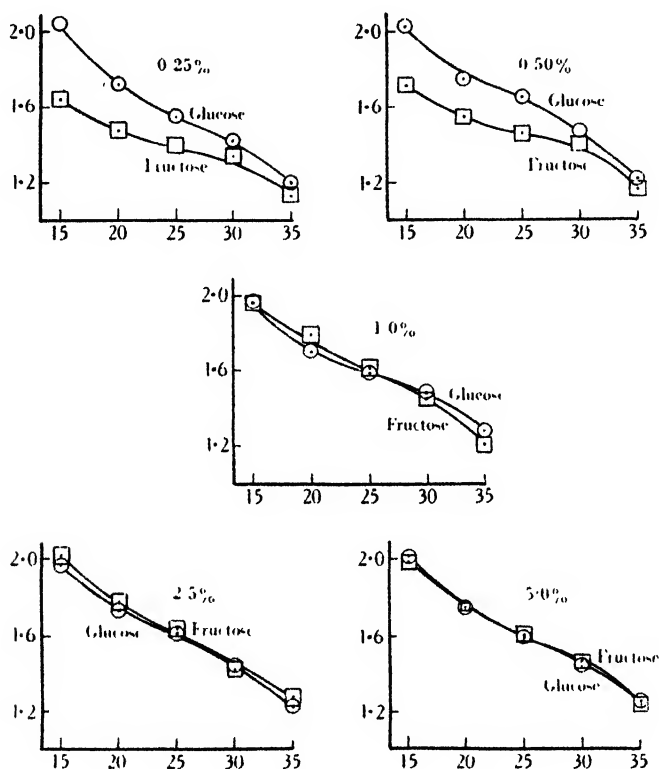

Fig. 1. Temperature coefficients  $V_{t+5}/V_t$  (ordinates). Temperature  $t^\circ$  (abscissae).

*Exp. 1.* Glucose or fructose 0.25–5.0 g. Pressed yeast 2 g. Temp. 15–40°. Total volume 100 ml.

Table 1. Temperature coefficients  $V_{t+5}/V_t$ .

Concentration of sugar	0.25%	0.50%	1.0%	2.5%	5.0%

35	1.13	1.18	1.21	1.27	1.23

## DISCUSSION.

The results show that the temperature coefficient of rate of fermentation of glucose over the range of temperature  $15^{\circ}$ – $40^{\circ}$  is independent of the concentration of glucose between 0.25 and 5.0%. The mean values, 2.0, 1.73, 1.60, 1.45 and 1.24 have been confirmed by other experiments. The corresponding results for fructose, however, exhibit an anomaly in the region of low concentration where the latter exerts the greatest effect on the rate of fermentation. At 1% concentration and above, the curves for fructose coincide with those for glucose, but below 1% concentration they fall below the latter, lower temperature coefficients being observed. The simplest explanation of this is that, with rise in temperature, the fermentable component in fructose solutions decreases in concentration. There are objections to this explanation, however, which may be dealt with in a later communication. However it can be shown here that there are good grounds for the view that the rate of fermentation of fructose at these low concentrations is actually limited by the rate of mutarotation, *i.e.* the rate at which the fermentable component is restored by change in the dynamic equilibrium.

If it be assumed that the sugar in solution at equilibrium contains one component which is specifically fermented and another or others which are not, then fermentation will result in the removal of the one component and its continual replacement from the other or others until exhaustion of the latter supervenes. If the concentration of total sugar is low enough, a limiting factor controlling the rate of fermentation will be the concentration of the fermentable component, and, unless its replacement is faster than its removal, the rate of mutarotation will become the controlling factor. The temperature coefficients of the latter factor are less than those of the rate of fermentation at normal concentrations of fructose but are reasonably close to those of fermentation of fructose at low concentrations. To ascertain the temperature coefficients of mutarotation of fructose, reference was made to the data furnished by Nelson and Beegle [1919], and the values calculated for  $p_H$  6.0–6.2. This is the value of the  $p_H$  of the contents of brewer's yeast cells observed by Tait and Fletcher [1926] and by Mahdihassan [1930]. It was assumed that all components of the sugar diffuse into the cell, the removal of the fermentable one takes place within, and its replacement follows from the sugar in the immediate vicinity, *i.e.* within the cell and therefore at a rate controlled by the reaction of the highly buffered cell contents. The temperature coefficients so obtained were:

$$k_{25}/k_{15} = 2.20; \quad k_{25}/k_{25} = 1.86.$$

These refer to the velocity constants of the mutarotation unimolecularly of  $\beta$  (2, 6)-fructose ( $[\alpha]_D - 130.8^{\circ}$  at all temperatures investigated) to equilibrium at the respective temperatures. But the equilibrium point varies with temperature so that the value of  $a$  in the equation  $k = \frac{1}{t} \ln \frac{a}{a-x}$  is different for the different temperatures. In calculating their velocity constants Nelson and Beegle put

$$a = \rho_0 - \rho_{\infty} \quad \text{and} \quad a - x = \rho - \rho_{\infty},$$

where

$\rho_0$  = initial specific rotation,

$\rho$  = specific rotation at time  $t$ ,

$\rho_{\infty}$  = specific rotation at equilibrium,

and

$\rho_{\infty}$  varies with temperature.

However the values of Nelson and Beegle's temperature coefficients can be shown to apply to this case as may be seen from the following considerations.

Consider a small quantity of fermentable component  $\delta x$  to have been removed from the solution at equilibrium, thus changing the specific rotation by an amount  $\delta\rho$ . The velocity at which this quantity will be restored will be  $k\delta\rho$ , since for a unimolecular reaction  $\frac{dx}{dt} = k(a-x)$ , and in this case  $a-x$  is denoted by  $\delta\rho$ . At temperatures  $T_1$  and  $T_2$  let the corresponding unimolecular velocity constants be  $k_1$  and  $k_2$ . Then the velocities at which  $\delta x$  of fermentable component will be restored will be  $k_1\delta\rho$  and  $k_2\delta\rho$  respectively, and the temperature coefficient

$$\frac{V_{T_1}}{V_{T_2}} = \frac{k_1\delta\rho}{k_2\delta\rho} = \frac{k_1}{k_2},$$

or

$$\frac{V_{T_1}}{V_{T_2}} = \frac{\left(\frac{dx}{dt}\right)_1}{\left(\frac{dx}{dt}\right)_2} = \frac{k_1(a_1 - x_1)}{k_2(a_2 - x_2)}$$

Integrating,

$$\frac{k_1}{k_2} = \frac{\ln a_1 - \ln(a_1 - x_1)}{\ln a_2 - \ln(a_2 - x_2)} \cdot \frac{t_2}{t_1}.$$

Since  $(a_1 - x_1)$  and  $(a_2 - x_2) = \delta\rho$  are small, their value approaches zero, and the value of their logarithm approaches  $-\infty$  so that this expression becomes  $\frac{t_2}{t_1}$ , or the inverse ratio of the times required at the respective temperatures to restore the same small quantity  $\delta\rho$  of fermentable component.

Comparing the temperature coefficients of the velocity constants of mutarotation to equilibrium of  $\beta$  (2, 6)-fructose and those of  $\alpha$ - or  $\beta$ -glucose, calculated similarly and derived from the data furnished by Nelson and Beegle, with those of the rate of fermentation reported above the following summary is obtained.

*Temperature coefficients.*

Mutarotation		Fermentation			
$\alpha$ - or $\beta$ -Glucose	$\beta$ (2, 6)-Fructose	$\alpha\beta$ -Glucose concentration	Equilibrium fructose concentration		
		0.25-5.0%	1.5%	0.25%	
$V_{25}/V_{15}$	2.47	2.20	3.46	3.46	2.38
$V_{35}/V_{25}$	2.43	1.86	2.32	2.32	1.85

It will be seen that the values of fermentation temperature coefficients for fructose at 0.25% concentration are much lower than the corresponding values for higher concentrations or the values for glucose. On the other hand they show a significantly close agreement with the corresponding temperature coefficients of rate of mutarotation of  $\beta$  (2, 6)-fructose. With concentrations not lower than 0.25% the rate of fermentation of  $\alpha\beta$ -glucose is not controlled by rate of mutarotation.

The general conclusion emerges that, of fructose in solution at equilibrium, one component only is specifically fermented, and this component is continually restored from the other component or components. If appropriate conditions are employed the rate of fermentation is actually limited by the rate of mutarotation. The conclusion is also implicit that the fermentable component is a relatively small proportion of the total sugar present.

SUMMARY.

1. The temperature coefficients of rate of fermentation of glucose and fructose solutions at equilibrium over the range 0.25 to 5.0% concentration and 15 to 40° have been determined.

2. Except in the case of fructose at concentrations as low as 0.5% or less, these temperature coefficients are in close agreement for either sugar and for any concentration.

3. In the case of fructose at 0.25% concentration the temperature coefficients of rate of fermentation are in significantly close agreement with the corresponding temperature coefficients of velocity of mutarotation of  $\beta$  (2, 6)-fructose to equilibrium.

4. It is inferred that, of fructose in solution at equilibrium, one component only is specifically fermented, and that the rate at which it is restored from the other components is the factor limiting the rate of fermentation when the concentration of sugar is as low as 0.25%.

# CCXCVIII. THE SUGGESTED RELATION BETWEEN CYSTINE AND VITAMIN B<sub>2</sub>.

BY FRANCIS THOMAS GARNET PRUNTY  
AND MARGARET HONORA ROSCOE.<sup>1</sup>

*From the Division of Nutrition, Lister Institute, London.*

*(Received September 30th, 1935.)*

It has been suspected that some of the diets used in vitamin work, which contain protein in the form of purified caseinogen, may be deficient in cystine. This is particularly the case with diets used in experiments with the B-vitamins, since those used in the study of the fat-soluble vitamins usually contain the B-vitamins in the form of yeast or yeast extracts, which are rich in cystine.

The realisation of this fact has led some workers to guard against the possibility of a deficiency by adding cystine to the diet [Jansen, personal communication; Block and Farquar, 1933] and has led others to consider whether the syndrome of growth failure and dermatitis, hitherto considered to be due to a deficiency of vitamin B<sub>2</sub>, may not in reality be due, in part, to a deficiency of cystine. This view has recently been put forward by Itter *et al.* [1935].

In 1932, with the idea of investigating this question, we studied the effect of variations in the cystine content of the diet on the growth of rats receiving different amounts of vitamin B<sub>2</sub> and on the dermatitis developing in rats deprived of this vitamin. Although it was found that one of the samples of purified caseinogen used had a low content of cystine, the deficiency of cystine in the diet was found to be slight, and no interrelation between cystine and vitamin B<sub>2</sub> could be found. The work was therefore not published. The results we obtained, however, partly confirm and partly extend the recently published work of Itter *et al.*, and as they lead us to different conclusions, it is now thought desirable that they should be published.

## METHODS.

Rats weighing 35–50 g., immediately after weaning, were fed on the experimental diets, which all contained caseinogen 20%, rice starch 60%, cotton-seed oil 15%, and salt mixture (McCollum's No. 185) 5%, and were cooked in a steamer for 3–5 hours with water. They were supplemented with daily doses of cod-liver oil and concentrates of vitamins B<sub>1</sub> and B<sub>2</sub>.

Three preparations of caseinogen were used and two of these were supplemented with extra cystine, making in all five different diets:

(1) Diet K, containing 0.019% cystine, made with purified caseinogen, "Glaxo physiological caseinogen, AB" of cystine content 0.11%.

(2) Diet P2L, containing 0.046% cystine, made with Lister Institute purified caseinogen [*v. Chick and Roscoe, 1928*] of cystine content 0.22%.

(3) Diet FL, containing 0.062% cystine, made with unpurified "Light white casein" of cystine content 0.32%.

(4) Diet CK, 0.269% total cystine, made with "Glaxo purified caseinogen" and 0.25% additional cystine.

<sup>1</sup> This work was carried out during the tenure of a Beit Memorial Research Fellowship.

(5) Diet CFL, 0.312 % total cystine, made with unpurified "Light white casein" and 0.25 % additional cystine.

The cystine used was *l*-cystine obtained from Hoffman-La Roche.

Vitamin B<sub>2</sub> was given in the form of Peters's concentrate from yeast [Chick and Roscoe, 1929]; this was found to contain 20 mg./100 g. of cystine, the daily dose of 0.1 ml. ( $\equiv$  0.6 g. dry yeast) thus providing 0.02 mg., a negligible amount.

Vitamin B<sub>2</sub> was given as various watery extracts from yeast, autoclaved either in an acid medium for 5 hours, or in an alkaline medium for 1 hour, in order to destroy vitamin B<sub>2</sub> [Roscoe, 1933, 2]. Both these preparations were found to contain 30 mg./100 g. of cystine, the daily doses of 0.5–1.0 ml. ( $\equiv$  0.25–0.5 g. dry yeast) containing 0.15–0.30 mg. of cystine. The presence of cystine in these autoclaved extracts is interesting, since it has been generally thought that such treatment would completely destroy this amino-acid.

The cystine estimations were carried out by the modified Sullivan method described by Prunty [1933]. This involves reduction of the cystine to cysteine, so that both amino-acids, if present, are estimated together.

The glutathione estimations were made according to the method of Tunnicliffe [1925]. The animals were anaesthetised with ether, the thorax was cut open and blood removed from the heart with a syringe, about 4 ml. being the amount obtained from a 100 g. rat. About 10 g. each of liver and muscle were removed as quickly as possible, weighed and ground with sand, the muscle having been first roughly chopped with scissors.

It was not found possible to make duplicate estimations so that it did not seem justifiable to calculate the results to smaller amounts than 10 mg./100 g.

## EXPERIMENTAL.

### A. *The effect of the proportion of cystine in the diet on the occurrence of dermatitis in rats deprived of vitamin B<sub>2</sub>.*

Itter *et al.* [1935], discussing the possible rôle of the sulphydryl group in vitamin B<sub>2</sub> deficiency, suggested that "the variability of the cystine content of different caseins may account for the inconstant results frequently observed in producing the deficiency". In support of this they quote the conclusion of Chick and Roscoe [1928], that in order to obtain dermatitis it was necessary rigidly to purify the caseinogen of the basal diet, which process would be liable to reduce the cystine content.

Roscoe [1933, 1] however, as the result of a more prolonged study, found that the purification of the caseinogen had no significant effect on the incidence of dermatitis. These results are given again in Table I, Exp. 1. Neither the number of rats developing dermatitis nor the time during which they received the deficient diet before symptoms developed was affected by the amount of cystine in the diet.

Table I. *Incidence of dermatitis and weight increase among rats deprived of vitamin B<sub>2</sub> and receiving diets containing varying amounts of cystine.*

Exp. No.	Diet	Cystine content of diet %	No. of rats observed	No. of rats developing dermatitis	% of rats developing dermatitis	Average time for development of dermatitis weeks	Average weight increase in 5 weeks g.
1	K	0.019	22	13	64	8	4
	P2L	0.046	107	61	57	11	8
	FL	0.062	54	36	67	9	20
2	FL	0.062	17	13	76	9	21
	CFL	0.312	11	8	73	9	19

In Table I, Exp. 2, are shown the results of a further small experiment, in which the diet FL and the same diet with added cystine (CFL) were fed to rats from the same litters. The incidence of dermatitis was in no wise affected by this addition to the diet.

*B. The effect of the proportion of cystine in the diet on the growth of rats.*

In the last column of Table I are shown the increases in weight of rats deprived of vitamin B<sub>2</sub> during the first 5 weeks of deficiency. It will be seen that, although the cystine content of the diet did not affect the incidence of dermatitis, it appears to have influenced the growth of the animals. Thus, in Exp. 1, the average weight increases observed during the 5 weeks were 4, 8 and 20 g. for rats receiving the diets containing 0.019, 0.046 and 0.062 % cystine respectively. Increasing the cystine content beyond this point (Exp. 2) from 0.062 to 0.312 % did not improve the growth and it may therefore be supposed that the 0.062 % level was adequate.

These results are striking, but it should be borne in mind that the different methods employed for purifying the caseinogen may have affected it in other ways than by altering the cystine content, and that the different rats included in Exp. 1 were not observed concurrently, but over a number of years, so that variations in their reserves and in other experimental conditions may possibly have had an effect on growth [*v. Chick et al.*, 1935].

Three more comparable experiments were carried out, in which rats received diets containing varying amounts of cystine together with sub-optimum amounts of vitamin B<sub>2</sub>. These results are given in Table II. In Exp. 3 the

Table II. *Weight increase of rats receiving diets containing varying amounts of cystine and varying sub-optimum amounts of vitamin B<sub>2</sub>.*

		Average	55	—
		—	—	—

\* These rats were observed for two periods of 5 weeks each.

addition of 0.25 % cystine to the diet FL containing unpurified caseinogen was again found to have no effect on weight increase. In Exps. 4 and 5, 0.25 % cystine was added to the diet K, containing the purified Glaxo caseinogen, whilst rats receiving the diet FL, containing unpurified caseinogen, were observed simultaneously as controls. In Exp. 4 a low level of vitamin B<sub>2</sub> was fed and there was a slight improvement in growth, 62 g. against 53 g. in 5 weeks, when the

additional cystine was given. In Exp. 5 where the vitamin intake was higher, there was no significant difference, the increase in weight with the extra cystine being 78 g. in 5 weeks, as against 75 g. In both Exps. 4 and 5 the growth of the rats receiving the Glaxo caseinogen diet supplemented with cystine was as good as that of the rats with the diet containing unpurified caseinogen.

It thus appeared that the purified Glaxo caseinogen diet and the Lister purified caseinogen diet did not contain enough cystine for the growth of young rats, but that this deficiency did not affect the occurrence of dermatitis due to vitamin B<sub>2</sub> deficiency.

*C. Glutathione content of the tissues of rats receiving synthetic diets.*

In most cases in which estimations have been made of the sulphhydryl content of the tissues of animals deprived of the B-vitamins, the animals were deprived of the entire vitamin B complex or of vitamin B<sub>1</sub> [Abderhalden and Wertheimer, 1923; Randoïn and Fabre, 1927; 1931; Drummond and Marrian, 1926]. The results have been, in any case, conflicting.

The effect of a diet low in cystine on the sulphhydryl content of tissues was also investigated by Abderhalden [1922], who found that tissues from rats on such diets gave a very weak nitroprusside reaction. In this case the animals were supplied with the B-vitamins.

Itter *et al.* [1935] found that rats fed on their experimental diet, containing purified caseinogen, showed variations in the glutathione content of the tissues which bore a relation to the vitamin B<sub>2</sub>-containing supplements fed. Thus when no vitamin B<sub>2</sub> was given, the average glutathione content of the blood was 29.4 mg./100 ml. and that of the liver 143 mg./100 g.; when 5% dried yeast was added to the diet, these amounts were increased to 40.0 mg. and 177 mg. respectively. Supplements of autoclaved yeast, of glutathione or of cysteine hydrochloride raised the glutathione level of the liver to the same extent as dried yeast but did not affect that of the blood.

The results which we obtained for the glutathione content of blood, liver and muscle, are given in Table III. They show that the glutathione content of the tissues was not influenced by the variations in the cystine content of the diets. It is possible, however, that had the amounts of cystine fed been still lower

Table III. *Glutathione content of the tissues of rats (ca. 100 g. weight) receiving diets containing varying amounts of cystine, with and without vitamin B<sub>2</sub> (1.0 ml. of autoclaved yeast extract containing enough vitamin to promote 50 g. weight increase in 5 weeks).*

Diet	Cystine content of diet %	Vitamin B <sub>2</sub>	No. of weeks during which diet was fed	Glutathione		
				Blood mg./100 ml.	Liver mg./100 g.	Muscle mg./100 g.
K	0.019	+	6	40, 40, 30	200, 180, 180	40, 40, 30
			13	40, 30	240, 150	30, 30
CK	0.269	+	6	40, 40, 30	190, 190, 160	40, 40, 30
			13	40, 40	170, 170	30, 30
FL	0.062	+	12	40, 40	230, 160	40, 30
			13	40, 30	190, 170	30, 30
		-	12	40, 40	230, 210	40, 30
Mixed stock diet			—	40, 30	240, 230	50, 30

there might have been a reduction in the glutathione levels, and the fact that Itter *et al.* observed values as low as 20 mg./100 ml. for blood and 100 mg./100 g. for liver, as compared with our lowest values of 30 mg. for blood and 150 mg. for liver, would seem to indicate that their purified caseinogen contained less cystine than did the Glaxo purified caseinogen used by us (see Diet K, Table III).

The two rats totally deprived of vitamin B<sub>2</sub> receiving the adequate cystine diet (FL) showed a glutathione content of the tissues as high as that of the animals receiving the same diet with sub-optimum amounts of the vitamin, or of those receiving an adequate stock diet. Thus, if a diet contained adequate cystine, it did not appear that the vitamin B<sub>2</sub> intake influenced the glutathione content of the tissues. Glutathione determinations could not be made on the tissues of rats receiving a cystine-deficient diet, without any vitamin B<sub>2</sub>, owing to the small size of these animals.

#### DISCUSSION.

The results described above confirm the fact that caseinogen, which in any case is not rich in cystine [Osborne and Mendel, 1915], may be so affected by the extraction and heating processes used during its "purification", that a level of 20% in the diet is no longer adequate for the growth of rats. The glutathione content of the tissues, however, was not found to be affected by a level of cystine intake which was sufficiently low to retard growth.

It may perhaps be noted that Osborne and Mendel found that 15% unpurified caseinogen in the diet was the lowest level which provided sufficient cystine for the normal growth of young rats. It is therefore to be expected that reducing the cystine content of the caseinogen by more than one quarter will produce a cystine deficiency when the caseinogen is fed at a 20% level.

From such results as these however it is impossible to compute accurately the quantitative needs of the rat for this amino-acid. Not only is there no accepted standard method of estimating cystine in biological materials, but as yet there is also no agreement as to the extent to which cystine and cysteine can be replaced by methionine. It has been suggested recently [Brand *et al.*, 1935] that cystine and glutathione are metabolised by a separate path from cysteine and methionine. If this holds true for normal animals as well as for those suffering from cystinuria, on which the experiments were performed, it would seem probable that even cysteine cannot replace cystine in the diet. In our work, which was carried out before the more recent papers on the subject were published, no distinction was made between cystine and cysteine, and methionine was not considered.

Although it must now be recognised that, in many cases, animals fed on diets thought to be complete in every factor except vitamin B<sub>2</sub> were in fact also inadequately supplied with cystine, it does not appear that this cystine deficiency materially affected the syndrome of vitamin B<sub>2</sub> deficiency.

Both cystine and vitamin B<sub>2</sub> are necessary for the growth of rats, and since a number of vitamin B<sub>2</sub>-containing substances are also rich in cystine, it is possible that quantitative errors have occurred in vitamin B<sub>2</sub> estimations in which the basal diet employed contained purified caseinogen. It is doubtful however whether these errors would have been large enough to be significant.

The only observation in our work which suggested that vitamin B<sub>2</sub> and cystine might have a supplementary action was the fact that the cystine inadequacy of the purified caseinogen diet (K) was less apparent at the higher levels of vitamin B<sub>2</sub> intake (see Table II). This effect was not due to the addition

of more cystine in increasing doses of autoclaved yeast extract, for the vitamin B<sub>2</sub> preparations used contained varying proportions of cystine. Thus the vitamin B<sub>2</sub>-containing dose given in Exp. 5, where the largest amount of vitamin B<sub>2</sub> was fed, contained less cystine (0.22 mg. daily) than the dose given in Exp. 4 (0.30 mg. daily), whilst the growth in Exp. 5 was definitely superior. It was however possible that this result might be explained by the fact that the rats receiving little or no vitamin B<sub>2</sub> ate poorly, whilst those receiving more vitamin B<sub>2</sub> ate more freely. In this way the cystine intake might be increased sufficiently to satisfy the physiological requirements.

Growth, being dependent on so many factors, is at best an unsatisfactory criterion for work of this type, and the absence of correlation between the cystine content of the diet and the incidence of vitamin B<sub>2</sub> deficiency dermatitis disproves any relationship between cystine and vitamin B<sub>2</sub> more clearly than can any observations on growth.

Our results do not agree with those of Itter *et al.* [1935], who found that the skin symptoms developed by their rats receiving a vitamin B<sub>2</sub>-deficient diet were cured by the addition of glutathione or cysteine hydrochloride to the diet. Our rats however exhibited an acute inflammatory dermatitis [Goldberger and Lillie, 1926; Chick and Roscoe, 1927; Roscoe, 1933, 1], described by György [1934] as the "specific" type of dermatitis, and by Chick *et al.* [1935] as the florid or (*a*) type. Rats developing the (*b*) type described by the latter workers, the "non-specific" type of György, were not included in our observations. The rats observed by Itter *et al.*, however, did not show a florid inflammatory dermatitis, and the alopecia they describe is not specific for vitamin B<sub>2</sub> deficiency and may be caused when rats, fed on any insufficient diet, pluck themselves or each other. Such a condition might well be cured more rapidly when cystine is added to the diet, since sulphur-containing amino-acids are needed for the growth of hair.

In our experiments the failure of large amounts of cystine ('FL diet) to prevent the occurrence of the dermatitis characteristic of vitamin B<sub>2</sub> deficiency would seem to indicate clearly that this type of skin lesion is not connected with cystine metabolism.

Since this work was carried out, vitamin B<sub>2</sub> has been resolved into two factors [Kuhn *et al.*, 1933, 1; 2; *etc.*], one factor being a lyochrome (flavin) and the second known as the supplement or vitamin B<sub>6</sub>. In our work, the effects stated to be due to absence of vitamin B<sub>2</sub> were due to absence of the whole vitamin B<sub>2</sub> complex, for it has been shown that the yeast concentrate used in this laboratory as source of vitamin B<sub>1</sub> contains no significant amounts of either flavin or supplement in the doses given. Separate experiments might therefore seem to be needed to show whether the failure of cystine to ameliorate symptoms of vitamin B<sub>2</sub> deficiency was due to the simultaneous need for another component of the complex. But it is obvious that cystine cannot take the place of either the flavin or the supplement, for Chick *et al.* [1935] have produced symptoms both of flavin deficiency and of supplement deficiency in rats fed on diets containing the unpurified "Light white casein" shown here to contain adequate amounts of cystine.

#### SUMMARY.

1. Confirmation has been obtained of the fact that some specimens of purified caseinogen, used in basal diets for vitamin work, are deficient in cystine.
2. When vitamin B<sub>2</sub> deficiency was complicated by a deficiency of cystine, to such an extent that growth was affected, the incidence of dermatitis was not influenced.

3. No relation has been found between cystine and the vitamin B<sub>2</sub> complex in the nutrition of the rat.

4. Within the limits observed, the cystine intake of rats was not found to influence the glutathione content of the tissues.

Our thanks are due to Dr H. Chick for advice and criticism.

# CCXCIX. KETOGENESIS-ANTI-KETOGENESIS.

## II. KETOGENESIS FROM AMINO-ACIDS.

By NORMAN LOWTHER EDSON.

*From the Biochemical Laboratory, Cambridge.*

*(Received September 30th, 1935.)*

THE fundamental facts of ketone-body formation from the amino-acids were established by Gustav Embden. The possible existence of a new factor arises from the work of Annau [1934], who discovered that ammonium chloride is a ketogenic agent in chopped liver. Recently the ammonia effect was examined in further detail with rat liver slices [Edson, 1935].

As a result it became important to decide if the ammonia which is liberated during deamination plays a ketogenic rôle in the intermediary metabolism of the amino-acids. This question was investigated by determining ketone-body formation in liver slices which were permitted to survive in phosphate-Ringer solution containing amino-acids. Since it is known that the naturally occurring stereoisomerides of the amino-acids are deaminated more slowly than the non-natural ones [Krebs, 1935], it was of interest to examine both series.

### *Methods.*

The methods employed, including those used for the estimation of ketone-bodies, have been described in earlier work [Edson, 1935]. As before the animals were young male rats (3-6 months) of a uniform laboratory strain. The liver slices (20-30 mg. dry weight) were immersed in 2 ml. phosphate-Ringer solution,  $p_H$  7.4, and shaken under an oxygen atmosphere for 2 hours in a thermostat at 37.5°. Respiration and acetoacetic ( $\beta$ -ketonic) acid production were measured as a routine.

Amino-acid solutions, 0.2  $M$ , were added to the Ringer solution in such quantities as to make a final concentration of 0.01 or 0.02  $M$ , except in those cases—tyrosine and cystine—where the solubility was very low, and then the Ringer solution was saturated with amino-acid at the temperature of the thermostat. Tyrosine and cystine were added as solids in amounts sufficient to give 0.01  $M$  solutions, but owing to the low solubility the saline remained saturated with excess substrate after 2 hours' contact with tissue. Slices which had been immersed in saturated solutions required thorough washing to remove solid particles. Histidine was used in a concentration of 0.005  $M$  because stronger solutions depressed respiratory activity. The dicarboxylic amino-acids were neutralised with sodium bicarbonate and the diamino-acids with HCl.

The values for  $\beta$ -ketonic acid production which are reported in this paper were determined manometrically by the aniline citrate method; but wherever possible they were checked by means of a modified Van Slyke procedure, which however is not applicable to the special cases of tryptophan, tyrosine, cystine and histidine.

*Units.* The tissue metabolism is expressed by the following quotients:

$Q_{O_2} = \mu l.$  oxygen consumption per mg. dry weight of tissue per hour.

$Q_{Acet.} = \mu l.$   $CO_2$  (acetoacetic ( $\beta$ -ketonic) acid) formed per mg. dry weight of tissue per hour. 1 millimol.  $\beta$ -ketonic acid = 1 millimol.  $CO_2$ .

## EXPERIMENTAL.

*Ketogenesis from the amino-acids.*

It was desirable to examine the antiketogenic properties of amino-acids in the liver of a starved animal as well as to investigate any ketogenic tendencies which they might have in the well-nourished organ. Accordingly the experiments were conducted in two separate series, one with rats which had been given full liberty to feed and the other with rats that had been starved for 24 hours.

(a) *The well-nourished animal.* In every case two controls were provided for comparison with the effect of the amino-acid: to one no substrate was added, and the other contained ammonium chloride in an initial concentration of 0.04 *M*. The results of typical experiments are collected in Table I.

When the data of Table I are examined the following points will be noticed:

1. The absolute values for acetoacetic (or  $\beta$ -ketonic) acid production from amino-acids which yield ketone-bodies are small and in no way comparable with those obtained when the substrates are fatty acids.

2. In the presence of tryptophan, proline, cystine, ornithine, lysine, aspartic acid and *l*(+)-isoleucine the values of  $Q_{\text{ket}}$  are no higher than those of the controls.

3. In accordance with the traditional view tyrosine, phenylalanine and leucine prove to be ketogenic.

4. Hydroxyproline, the ultimate fate of which is not recorded in the literature, is ketogenic to about the same degree. The remaining amino-acids—glycine, alanine, serine,  $\alpha$ -aminobutyric acid, valine, norleucine, *d*(-)-isoleucine, methionine, glutamic acid, histidine and arginine—present low values of  $Q_{\text{Acac}}$ , which nevertheless are higher than those of the controls.

5. If the ketogenic effect of amino-acids be compared with that of 0.04 *M* ammonium chloride, it is observed that tyrosine, phenylalanine, *dl*-leucine and hydroxyproline give values of  $Q_{\text{Acac}}$  of the same order;  $Q_{\text{Acac}}$  for *l*(-)-leucine is somewhat lower but in the case of all other amino-acids the quotients for ketone-body formation are lower than those for ammonium chloride.

In this work the term "ketogenic" has been used to denote an agent which increases the yield of ketone-bodies in living tissues. This does not necessarily mean that the substance itself is converted into ketone-bodies, *e.g.* certain amino-acids are ketogenic although the carbon skeleton does not form ketone-bodies.

(b) *The starved animal.* The series was repeated on rats which had been starved for 24 hours. Representative results are shown in Table II. Ammonium chloride controls were omitted, because ammonia has no ketogenic action on starved liver in the absence of substrate.

With regard to the starved animal the following points are noteworthy:

1. The only amino-acid which is markedly ketogenic is *dl*-leucine.

2. Certain amino-acids appear to be neither ketogenic nor ketolytic. They are *l*(+)-valine, *l*(-)-methionine, cystine, hydroxyproline and tyrosine.

3. The rest present antiketogenic properties which vary in degree but are best exemplified by arginine and ornithine.

Table I. *Ketogenesis from amino-acids in liver slices of well-nourished rats.*

## SOME SPECIAL PROBLEMS.

(a) *The catabolism of phenylalanine in liver.*

Embden and Baldes [1913] have shown that phenylpyruvic acid does not yield ketone-bodies in the perfused liver, whereas phenylalanine does. They concluded that phenylpyruvic acid is not an intermediate in the breakdown of phenylalanine. On the other hand Embden *et al.* [1906] found that  $\beta$ -phenyl-lactic acid gave acetoacetic acid, and it was assumed by them to be the more probable intermediate.

Both these substances have been added to the liver slices of a well-nourished rat, and the effects examined in presence and in absence of ammonium chloride. The results are given in Table III. Phenylpyruvic acid was prepared by the method of Erlenmeyer [1892]; m.p. 153°.  $\beta$ -Phenyllactic acid was the product of Fränkel and Landau; m.p. 98°.

Table III. *Formation of ketone-bodies from phenylpyruvic and phenyllactic acids in the liver of the well-nourished rat.*

Substrate	Respiration	Ketone-body formation
	$Q_{O_2}$	$Q_{Acac}$
Nil	- 12.3	0.45
Phenylpyruvic acid, 0.01 <i>M</i> (sodium salt)	- 11.7	0.48
Phenylpyruvic acid, 0.01 <i>M</i> (sodium salt) + $NH_4Cl$ , 0.04 <i>M</i>	- 8.0	0.88
$NH_4Cl$ , 0.04 <i>M</i>	- 11.0	1.02
Nil	- 10.0	0.33
$NH_4Cl$ , 0.04 <i>M</i>	- 9.8	1.10
$\beta$ -Phenyllactic acid, 0.01 <i>M</i> (sodium salt)	- 10.7	0.35
$\beta$ -Phenyllactic acid, 0.01 <i>M</i> (sodium salt) + $NH_4Cl$ , 0.04 <i>M</i>	- 8.6	1.14

The figures show that neither phenylpyruvic acid nor phenyllactic acid can be intermediates in the catabolism of phenylalanine, since they fail to give acetoacetic acid under conditions in which phenylalanine does so readily. The increased yields in the presence of ammonia are merely due to ammonia ketogenesis which always occurs even in the absence of added substrate. Embden's results with phenyllactic acid may be explained by the fact that he perfused with the ammonium salt of the acid.

It will be shown in a succeeding section that the path of phenylalanine catabolism in liver lies more probably through tyrosine and *p*-hydroxyphenylpyruvic acid.

Table IV. *Formation of ketone-bodies from p-hydroxyphenylpyruvic, homogentisic and muconic acids in rat liver slices.*

Animals well fed.		
Substrate	Respiration	Ketone-body formation
	$Q_{O_2}$	$Q_{Acac}$
Nil	- 13.9	0.45
$NH_4Cl$ , 0.04 <i>M</i>	- 11.0	1.02
<i>p</i> -Hydroxyphenylpyruvic acid, 0.01 <i>M</i> (sodium salt)	- 14.6	0.97
Ditto + $NH_4Cl$ , 0.04 <i>M</i>	- 15.0	2.76
Nil	- 11.7	0.26
$NH_4Cl$ , 0.04 <i>M</i>	- 9.2	0.77
Homogentisic acid, 0.01 <i>M</i> (sodium salt)	- 15.1	1.11
Ditto + $NH_4Cl$ , 0.04 <i>M</i>	- 11.2	1.98
Nil	- 13.6	0.21
$NH_4Cl$ , 0.04 <i>M</i>	- 9.0	0.55
Muconic acid, 0.01 <i>M</i> (sodium salt)	- 11.8	0.33
Ditto + $NH_4Cl$ , 0.04 <i>M</i>	- 8.9	0.72

Note: The apparent  $Q_{O_2}$  for homogentisic acid is a little too high, because slow autooxidation occurs in phosphate-Ringer solution at  $p_H$  7.4. The autooxidation accounts for about 6% of the total oxygen uptake.

(b) *The catabolism of tyrosine in liver.*

(1) *Ketone-body formation.* Certain substances which have been suggested as intermediates of tyrosine metabolism were examined in a similar way. *p*-Hydroxyphenylpyruvic acid and homogentisic acid formed large amounts of acetoacetic acid whether ammonium chloride was present or not, which is in agreement with previous perfusion experiments. Muconic acid gave little or none, and therefore it is not a possible intermediate (Table IV). Hensel and Riesser [1913] obtained acetoacetic acid on perfusing the liver with muconic acid, but, since they employed the ammonium salt, their conclusions are not valid.

*p*-Hydroxybenzamidocinnamic acid was prepared by the method of Erlenmeyer and Halsey [1899], and *p*-hydroxyphenylpyruvic acid was obtained from it by the method of Neubauer and Fromherz [1910]. M.P. 213°. Homogentisic acid was separated from alcaptonuric urine according to Garrod [1899] and Orton and Garrod [1901]; M.P. 152°. Muconic acid was synthesised by the method of Behrend and Koolman [1912]; M.P. 293°.

(2) *The oxidation of l(-)-tyrosine.* Bernheim and Bernheim [1934] state that *l*(-)-tyrosine is oxidised by liver "brei" in such a way that one molecule of tyrosine takes up four atoms of oxygen. Experiments were performed with rat and rabbit liver "brei" under the conditions stipulated by Bernheim and Bernheim. It was found however that there was no constancy in the additional oxygen uptake, which never exceeded two atoms of oxygen for one molecule of tyrosine; and the additional oxygen consumption was such a small fraction of the blank that the measurements possessed no great accuracy.

(c) *Relationship of phenylalanine to tyrosine.*

The following facts are relevant to a discussion of phenylalanine and tyrosine metabolism:

1. Both phenylpyruvic acid and phenyllactic acid, like phenylalanine, cause an increased elimination of homogentisic acid in the alcaptonuric patient [Neubauer and Falta, 1904]. In one particular individual phenylpyruvic acid was converted quantitatively into homogentisic acid, but of the administered phenyllactic acid only 41.5% was recovered as homogentisic acid.

2. Phenylpyruvic acid and phenyllactic acid, unlike phenylalanine, do not give rise to acetoacetic acid in liver.

3. *p*-Hydroxyphenylpyruvic acid and homogentisic acid form large amounts of acetoacetic acid both in perfused liver and in slices.

4. Embden and Baldes [1913] have demonstrated that a certain amount of *l*(-)-tyrosine is formed along with acetoacetic acid when the liver is perfused with *dl*-phenylalanine.

5. Following the oral administration of phenylalanine to rabbits the urine has been found to contain *p*-hydroxyphenylpyruvic acid (as well as phenylpyruvic acid) [Kotake *et al.*, 1922]. Shambaugh *et al.* [1931] and Chandler and Lewis [1932] have reported the results of injecting rabbits subcutaneously with phenylalanine and tyrosine. After phenylalanine injection significant amounts of phenylpyruvic acid were excreted but no *p*-hydroxyphenylpyruvic acid. The latter was not obtained even after administration of tyrosine.

6. Medes [1932] described a rare metabolic anomaly, tyrosinosis, in which it was discovered (amongst other phenomena) that the ingestion of phenylalanine was followed by an increased excretion of *p*-hydroxyphenylpyruvic acid and of tyrosine.

7. In the condition of imbecillitas phenylpyruvica, recently described by Fölling [1934], phenylpyruvic acid is excreted continuously.

From these facts certain conclusions may be drawn:

(1) Phenylpyruvic acid can arise from phenylalanine. This may be the preferential path of breakdown in kidney [Krebs, 1933].

(2) Since phenylpyruvic acid fails to yield acetoacetic acid in liver, there must be another catabolic path for phenylalanine.

(3) The evidence leads to the assumption that tyrosine is the intermediate. This is not merely in agreement with all experimental observations, but it is proved by the perfusion work of Embden and Baldes and by the observations of Medes on tyrosinosis. It is possible that the metabolic error of imbecillitas phenylpyruvica is a failure of the conversion of phenylalanine into tyrosine, but it may be a block of an alternative path.

*The rôle of ammonia in ketogenesis from amino-acids.*

A number of amino-acids caused a small but distinct increase in ketogenesis in cases where the carbon skeleton could not of itself give rise to  $\beta$ -ketonic acid, e.g. valine, glycine, serine. In these instances the ketogenic effect of ammonia liberated during deamination can explain the results. Where ammonium chloride was added a much greater value was obtained due to the high initial concentration (0.04 *M*). Since the liberation and removal of ammonia are concurrent processes of normal metabolism, the intracellular concentration cannot approach 0.04 *M*, but it seems reasonable to argue that ammonia could cause effects of the observed order of magnitude.

The antiketogenic influence of arginine and ornithine is interesting in this connection. It may be assumed that these substances lower the effective concentration of ammonia by promoting urea synthesis.

Comparison of the more rapidly deaminated amino-acids of the *d*-series with those of the *l*-series did not lead to any positive general conclusions. In cases where the carbon skeleton was non-ketogenic the *d*-amino-acids as a group were no more ketogenic than the members of the *l*-series.

SUMMARY.

1. The formation of ketone-bodies from amino-acids has been studied with rat liver slices, and in general the results confirm the perfusion work of Embden. The most strongly ketogenic amino-acids are leucine, tyrosine and phenylalanine.

2. The only other amino-acid which is considerably ketogenic is hydroxyproline.

3. Of the remaining amino-acids some are non-ketogenic, but others show a small ketone-body formation, which seems to be due to ammonia liberated in their metabolism.

4. A difference was observed between the fed and the starved animal. With the exception of leucine, tyrosine, phenylalanine and hydroxyproline the amino-acids show no marked ketogenesis in the fed rat; *dl*-leucine alone is ketogenic in the starved animal, whilst many others are antiketogenic.

5. The evidence relevant to the breakdown of phenylalanine has been discussed. Two pathways of phenylalanine catabolism are possible:

(i) Conversion into tyrosine and breakdown through *p*-hydroxyphenylpyruvic acid and homogentisic acid, which takes place in the liver, and

(ii) Primary deamination and formation of phenylpyruvic acid.

6. Muconic acid, contrary to statements in the literature, is not ketogenic. Previous results are due to use of the ammonium salt.

I wish to thank Dr H. A. Krebs for his kind interest in this work and for constant advice; Dr N. W. Pirie for samples of pure *dl*- and *l*(-)-cystine and *dl*-tyrosine; and Mr D. D. Woods for a specimen of pure *l*(-)-tryptophan.

# CCC. A NOTE ON THE LEVEL OF CARBONYL COMPOUNDS IN HUMAN BLOOD.

By ROBERT EUGENE JOHNSON, ARNOLD PETER MEIKLEJOHN,  
REGINALD PASSMORE AND  
ROBERT HENRY STEWART THOMPSON.

*From the Department of Biochemistry, Oxford, and the Department  
of Pathology, Guy's Hospital, London.*

*(Received October 1st, 1935.)*

IN view of the results obtained by Thompson and Johnson [1935] for the level of pyruvic acid in the blood of normal and vitamin B<sub>1</sub>-deficient pigeons and rats it was of interest to investigate the level of this compound in human blood. Thompson and Johnson showed that the concentration of pyruvic acid in the blood of avitaminous pigeons was very substantially higher than the normal level; the figures obtained were, for the normal, 0.84 mg. of pyruvic acid per 100 g. of blood, and for the avitaminous 5.65 mg. per 100 g. of blood, as estimated by the extraction of the 2:4-dinitrophenylhydrazone [see Case, 1932; Peters and Thompson, 1934].

The following communication is a note on the level of the total bisulphite-binding substances present in human blood. As in the previous work with animals, bisulphite-iodine titrations were first carried out on the blood filtrates before embarking on the more elaborate method of extraction of the hydrazones. In this work on human blood however bisulphite-iodine titration gave no indication of raised blood-pyruvate levels in any of the diseased conditions examined, so that hydrazone extractions have not been carried out. Several attempts were made to apply the full method of Clift and Cook [1932] for determining pyruvic acid, but in every case it was found that the titre was increased on heating, owing presumably to the formation of bisulphite-binding compounds from the sugars and amino-acids present, since Engfeldt [1920] observed that the amino-acids in blood filtrates break down to form acetone when heated in alkaline solution. It was also found that trichloroacetic acid (used as the protein precipitant) produced bisulphite-binding substances on heating: Merck's, Kahlbaum's and B.D.H. samples all gave this effect. For these reasons the titrations were limited to estimations of the total bisulphite-binding capacity of the blood filtrates.

*Method.* The method employed was as follows. Venepuncture was made with a medium-sized needle into one of the arm veins. About 3 ml. of blood were allowed to drip into a weighed centrifuge-tube containing 3 ml. of 25 % trichloroacetic acid and 4 ml. of water. (In some experiments a syringe was used, and the blood was squirted into the tube.) The tube was then re-weighed and the precipitate re-extracted in the same way as described for pigeon's blood. The combined centrifugates were then brought to  $p_H$  2.0 with 20 % sodium hydroxide, made up to 25 ml. and titrated for bisulphite-binding capacity.

*Results.* The results obtained for normal blood are given in Table I.

From these figures it may be seen that the results obtained for normal blood fall within strikingly narrow limits. The centrifugates were also tested for the presence of acetone bodies by means of the nitroprusside reaction, but in none

Average 2.81

of these cases a positive result obtained, so that no very high concentration of these substances can have been present. Furthermore, the careful work of Engfeldt [1920] provides an upper limit for the level of acetone bodies in the blood of normal human subjects in terms of *N*/100 iodine, which is of particular interest when reviewed in connection with our figures for the iodine titration of the total carbonyl compounds present. Engfeldt found, from his titrations of acetone bodies, that 2 ml. of normal human blood never have a titration of more than 0.05 ml. *N*/100 iodine, i.e. 100 ml. of normal blood have a maximum content of acetone bodies equivalent only to 2.5 ml. *N*/100 iodine.

If we now make use of the figures obtained by Arndt [1921] for the specific gravity of whole blood (1.02), we find that the upper limit of the level of acetone bodies in normal blood, according to Engfeldt's figures, is equivalent to 2.45 ml. *N*/100 iodine per 100 g. of blood. The average level presented above for the total bisulphite-binding capacity of human blood when reconverted into iodine values is equivalent to 6.39 ml. *N*/100 iodine per 100 g. of blood. We find therefore a concentration of carbonyl compounds in normal human blood, over and above that of the acetone bodies, equivalent to 3.94 ml. *N*/100 iodine per 100 g. of blood, or expressed in terms of pyruvic acid, 1.73 mg. per 100 g. blood. Moreover, it must be remembered that Engfeldt's figures include  $\beta$ -hydroxybutyric acid, which is not estimated by our method, so that the level of carbonyl compounds over and above that of acetone and acetoacetic acid is, in reality, slightly higher than the figure given above.

Although hydrazone extractions have not been carried out, the nitroprusside reaction of Simon and Piaux [1924] has been watched in every experiment, but in none of the experiments on normal blood did a positive reaction develop. On working out the lower limit of sensitivity of this reaction, however, we have found that this agreed with our level of "non-acetone body" carbonyl compounds calculated from Engfeldt's results. The lower limit of the reaction was found by us to be given by a concentration of pyruvic acid of about 2 $\gamma$  per ml., and a concentration of this order in the final centrifugates in which the reaction was carried out would correspond to a level of 1.64 mg. per 100 g. of blood, whilst our level of "non-acetone body" carbonyl compounds was found to be only 1.73 mg. per 100 g. of blood. On the other hand it must be remembered that this level found by us is, owing to the inclusion of  $\beta$ -hydroxybutyric acid in Engfeldt's figures, in all probability too low, so that it seems probable that there may exist in normal human blood detectable amounts of some carbonyl compound other than pyruvic acid, acetone, or acetoacetic acid.

In view of the known relationship between pyruvic acid and brain metabolism [Peters and Thompson, 1934] estimations were also done on the blood of patients suffering from various forms of insanity (see Appendix), but although in several instances high values were obtained it was impossible to conclude that in any of the conditions examined was there any statistical difference from the normal level.

The blood was also examined from a number of hospital patients suffering from physical disease (see Appendix), including some whose conditions were suggestive from the point of view of their symptomatology of a vitamin B<sub>1</sub> deficiency, but here also no true evidence of a raised level was obtained. We have been unable to procure any cases of beri-beri for inclusion in our results, but we are of the opinion that it is of value in view of future work on this condition to publish these results obtained with normal blood.

We wish to express our sincere gratitude to Prof. R. A. Peters for the help and advice which he has given us throughout the course of this work and to Prof. G. P. Wright and Dr K. O. Newman for the facilities which have been placed at our disposal at Guy's Hospital, Pathology Department, and at the Littlemore Mental Hospital, Oxford, respectively.

#### APPENDIX.

The following table shows the results obtained on the blood of patients suffering from mental and physical disease. As already mentioned the figures show no significantly raised level of bisulphite-binding substances, and are merely included in order to show the variations of the values obtained.

# CCCI. FURTHER OBSERVATIONS ON THE CONSTITUENTS OF THE UNSAPONIFIABLE FRACTION OF WHEAT GERM OIL WITH PARTICULAR REFERENCE TO VITAMIN E.

BY JACK CECIL DRUMMOND, ELEANOR SINGER  
AND ROY JAMES MACWALTER.

*From the Department of Biochemistry, University College, London.*

*(Received October 1st, 1935.)*

## *The hydrocarbons of wheat germ oil.*

IN a previous paper [1935] we described hydrocarbons separated from wheat germ oil unsaponifiable matter in fractions which either were not adsorbed or but slightly adsorbed by aluminium oxide from solution in light petroleum. One fraction seemed to consist mainly of a compound of molecular weight about 250, B.P. 120–140°/0.05 mm., probably saturated.

Larger quantities of this material have now been prepared and examined. When first obtained the iodine values of this fraction are usually about 30–40, but that a highly unsaturated contaminant is present is shown by bromination in dry ethereal solution at  $-18^{\circ}$  when an insoluble bromide is deposited. The properties of this derivative suggest its identity with the bromide of the hydrocarbon ( $C_{45}H_{76}$  or  $C_{50}H_{84}$ ) isolated from mammalian livers by Channon and Marrian [1926] and Channon *et al.* [1934]. Considerable amounts of this highly unsaturated hydrocarbon are found in an adjacent wheat germ oil fraction. Channon *et al.* [1934] believe that under appropriate conditions the preparation of the bromide is almost quantitative and that it is not significantly inhibited by the presence of other substances. Bromination of our fractions under the conditions they describe did not remove more than half the unsaturation. Other attempts to separate the unsaturated contaminant, such as by partition between solvents, were no more successful and we were seldom able to reduce the iodine value below 15–20. Efforts were then made to purify the saturated hydrocarbon fraction by distillation.

In every case the course of the distillation indicated that the material was a mixture. Unfortunately the amounts available were insufficient to permit satisfactory refractionation, but strong indications were obtained that two hydrocarbons predominated. Thus in one redistillation of 4.3 g. at 0.03 mm. three fractions were obtained: (i) 118–130°, 1.4 g.; (ii) 130–150°, 0.12 g.; (iii) 150–165°, 1.6 g. Several preparations of the lowest-boiling fractions were obtained in the form of a colourless limpid oil which solidified just below zero. A number of the elementary analyses were unsatisfactory as it was found very difficult to prepare material entirely free from an oxygen-containing impurity. Four acceptable analyses gave the figures: C, 84.89, 85.17, 85.18, 85.45%; H, 14.85, 14.72, 14.81, 14.42%; Mean values. C, 85.12%; H, 14.45%; mol. wt. 254, 274, 261, 251. Mean 260.

These figures would satisfy the formula  $C_{18}H_{38}$  (mol. wt. 254; C, 85.04%; H, 14.96%). We thought at first that the substance might be identical with

isooctadecane (pristane) isolated by Toyama [1923] from a number of shark-liver oils; an interesting possibility because of association in both instances with hydrocarbons of the squalene type. There are however differences which seem to point to the compounds being distinct. For example, our hydrocarbon has a refractive index  $n_D^{20}$  1.4722, higher than that recorded for pristane. The purified hydrocarbon is optically inactive and shows no absorption bands in the ultra-violet. The bands recorded for the impure preparations described in our earlier paper are now known to be due to traces of substances of low volatility, probably of the sterol family.

The higher-boiling material (iii) of this hydrocarbon fraction has also proved difficult to free from oxygen-containing impurities sufficient in amount to disturb the analytical figures. The fractions were all optically inactive and spectroscopically transparent.

Four satisfactory analyses gave the figures: C, 86.48, 86.45, 86.53, 86.39%; H, 13.21, 13.51, 13.34, 13.23%; mol. wt. 261, 274, 260, 294. Mean values. C, 86.46%; H, 13.32%; mol. wt. 272;  $n_D^{20}$  1.4729. These fractions invariably gave iodine values of the order of 30–40. It is uncertain at present whether this material is a saturated hydrocarbon contaminated with a small proportion of a highly unsaturated hydrocarbon which, under the conditions employed by us, is not precipitated on bromination, or whether a considerable proportion of a less unsaturated compound is present. In this connection the observations of Channon *et al.* [1934] on the presence in pig-liver of hydrocarbons of rather similar character are of interest.

The highly unsaturated hydrocarbon fraction (B) previously separated by us from wheat germ oil unsaponifiable has also been further studied. The fraction is that which can be washed out of the aluminium oxide column by light petroleum and it is characterised by high iodine values, 180–240. In our former study we detected squalene in this material and also thought that it might contain the hydrocarbon ( $C_{45}H_{76}$  or  $C_{50}H_{84}$ ) which Channon and Marrian [1926] first isolated and which appears to be of the squalene type. This we can now confirm. The amounts of squalene seem to vary in different specimens of wheat germ oil but in most cases they are small compared with those of the other hydrocarbons. In some cases indeed it was difficult to separate the characteristic hydrochloride of the former compound. The fraction as a whole usually gave a yield of hydrochloride or bromide corresponding to about 25% of its weight as  $C_{45}H_{76}$ . Both hydrochloride and bromide are micro-crystalline and the latter is unusually difficult to purify. Typical analyses are:

*Hydrochloride.* m.p. 116–120°; Cl, 31.56, 31.34, 31.16, 31.39%. Calculated for  $C_{45}H_{76} \cdot 8HCl$ ; Cl, 31.2%.

*Bromide* darkening about 120° and becoming black with decomposition at 160–180°. Br, 67.7, 67.34, 67.54, 67.4%. Calculated for  $C_{45}H_{76} \cdot 16Br$ ; Br, 67.7%.

It is doubtful whether the unsaturation shown by fraction B can be entirely attributed to these hydrocarbons. In the first place, in view of the fact that Channon and his colleagues obtained quantitative precipitation of  $C_{45}H_{76}$ , our yields of bromide are too small. Moreover, as was tentatively suggested in our former paper, there is evidence of the presence of rather highly unsaturated substances containing oxygen in these fractions. Fractions readily soluble in methyl alcohol have been prepared. These have iodine values as high as 200 and are now being investigated.

From a number of examinations of wheat germ oil unsaponifiable we estimate that the saturated  $C_{18}$  and the unsaturated  $C_{45}H_{76}$  hydrocarbons are present to the extent of approximately 3 and 7% respectively.

*The vitamin E fraction.*

Larger quantities of this fraction prepared as described in our earlier paper have been investigated. We have confirmed the occurrence of  $\beta$ -amyrin, but find that the amount associated with the vitamin may vary considerably with preparations from different oils. It is without effect when administered to vitamin E-deficient rats.

*A new sterol.*

The vitamin fraction contains a sterol-like substance which does not appear to have been described before. It escaped notice in our previous investigation because we unwisely assumed that the material removed from the vitamin fraction by precipitation with digitonin was the common "sitosterol mixture", of which so much is found in the original unsaponifiable matter. Having in this case a larger amount of the digitonide precipitate the substance in question was recovered by xylene treatment. With a reservation prompted by knowledge of the great difficulty of purifying small quantities of sterols we are inclined to believe that it consists almost entirely of one compound. Crystallised from ethyl or, more satisfactorily, methyl alcohol, it separated as a curious gelatinous mass; a behaviour recalling that of lanosterol. On microscopic examination the solid was found to consist of very minute spherulites of needle-shaped crystals. Recrystallisation did not raise the melting point beyond 105–106°, but the amounts did not permit exhaustive fractionation. It was optically active  $[\alpha]_D^{20} + 58.5^\circ$  (benzene) and spectroscopically transparent. The acetate, which crystallises more satisfactorily in clusters of fine needles from methyl alcohol solution, melts at 98–100° and shows  $[\alpha]_D^{20} + 65.7^\circ$  (benzene).

The dinitrobenzoate darkened at 90°, contracted at 130°, and finally melted fairly sharply at 156–158°;  $[\alpha]_D^{20} + 56.9^\circ$  (benzene).

The mean figures given by seven determinations of elementary composition were: C, 81.66%; H, 11.4%; mol. wt. 425; Acetate: C, 78.86%; H, 10.52%; mol. wt. 462.

These figures correspond fairly well with a compound of formula  $C_{29}H_{48}O_2$ , (C, 81.3%; H, 11.21%; mol. wt. 428), giving a monoacetate (C, 79.15%; H, 10.64%; mol. wt. 470). The values obtained in determinations of acetyl groups also confirm that one is present. The iodine value found, 109, points to two ethylenic bonds; calculated value 118. We are, however, not entirely satisfied with the formula suggested.

The behaviour of this compound with some colour reagents for the sterols recalls that of lanosterol. *Salkowski*; after a time the acid layer acquires a pale orange-yellow colour with green fluorescence; *Liebermann-Burchard*; slow development of brown-red colour with strong green fluorescence; *Whitby's B*; slow development of pinkish red colour; *methyl sulphate*; no colour in the cold but a pale brownish red on gentle warming; *benzoylperoxide*: pale straw-yellow with very slight green fluorescence.

We are investigating the chemical nature of this interesting compound further but meanwhile it is important to record that it was found of no value in counteracting vitamin E-deficiency in female rats.

*Further investigation of vitamin E.*

In our previous study we described the preparation from this fraction of concentrates of the vitamin of which the most potent protected rats in daily doses of 0.1 mg. Evans and Burr [1927] showed that the physiological effect of a single dose of a vitamin E concentrate given at, or shortly after, the time of positive mating is indistinguishable from that produced by the same amount given in a

number of doses spread over the whole period of pregnancy. Our own experiments support this view. The total dose of the concentrate referred to can therefore be placed as 2 mg. In the present communication all dosages given are "total" doses.

It was reported that the active fractions showed a well marked absorption with a maximum at  $294m\mu$  and a minimum at  $267m\mu$ , and that during fractionation and concentration the vitamin activity tended to run parallel with the intensity and persistence of the band. From the behaviour on acetylation it was tentatively suggested that the substance giving rise to the band might be a cyclic ketone capable of showing keto-enol change.

Attempts were therefore made to separate ketonic material from the concentrate by employing the methods of Girard [1933: Girard and Sandulesco, 1934] and of Beall and Marrian [1934]. As reported in our previous paper the ketonic fractions separated in this manner did not show the selective absorption in the ultraviolet. We can now report that they did not exercise the biological activity of vitamin E.

During the examination of these fractions for the presence of ketonic substances it was observed that they gave positive responses to colour tests such as that with *m*-dinitrobenzene [von Bittó, 1897; Zimmermann, 1935]. Efforts were therefore made to isolate an oxine or a semicarbazone but without success, although definite evidence of combination with these reagents was obtained. As far as could be judged about 8% of the material combined and it is interesting that the ketonic fractions separated by the use of the reagent of Girard and of Beall and Marrian represented about the same proportion (8–10%).

With 2:4-dinitrophenylhydrazine sulphate in acid alcohol a small quantity of a scarlet coloured derivative was obtained but the amount was only sufficient for one recrystallisation from methyl alcohol and for one elementary analysis. The product was micro-crystalline and its colour indicated an unsaturated ketone. It melted at  $118-120^\circ$  and had C, 69.92%; H, 8.46%; N, 9.43%. These values would correspond with a molecule of the cholestenone type.

The material left behind after separation of the dinitrophenylhydrazone and removal of the excess of reagent showed the characteristic band at  $294m\mu$ , although in diminished intensity. These observations were sufficient to dispel the view that the substance responsible for the band contains an active ketonic grouping. In attempting to carry the concentration further the next step was to remove the  $\beta$ -amyrin, which is often rather closely associated in adsorption experiments with the vitamin fraction. In the earlier experiments this was effected by acetylation,  $\beta$ -amyrin acetate being so sparingly soluble in alcohol that separation is almost quantitative. It was found however on hydrolysing the residue by means of hot alcoholic potash that the intensity and persistence of the band at  $294m\mu$  were lower than before acetylation. There was also evidence that the biological activity had been reduced. This observation occasioned surprise because in our experience we had not found the vitamin to be injured by such treatment, recovery from the products of saponification of wheat germ oil having always been satisfactory. Recently however Evans *et al.* [1935] have published convincing evidence that treatment with hot alkalis may under some conditions inactivate the vitamin: previous work in their laboratory had aroused a suspicion that unexpectedly large losses sometimes occurred during saponification [Evans, 1932].

Instead of removing  $\beta$ -amyrin by acetylation therefore we had recourse to fractional distillation at low pressure ( $<0.0001$  mm.). For this we employed an apparatus originally designed for the separation of vitamin A [Heilbron *et al.*, 1932]. Although this apparatus enables satisfactory fractionations to be carried

out it failed to give the desired results in that investigation because the vitamin A molecule underwent a change, probably, it is thought, of the nature of a cyclisation as a consequence of exposure to a relatively large surface of heated glass.

In the present case we at first concluded that no such change occurred from the fact that satisfactory concentrations of the substance responsible for the 294  $m\mu$  band were obtained.

The course of the distillation and the yield of the various fractions indicated that there was no appreciable loss of the substance responsible for the band.

Stage of fractionation	$E_{1\%}^{1cm}$		Ratio
	294 $m\mu$	267 $m\mu$	
2nd adsorption on $Al_2O_3$	33	15.5	2.1
1st distillation	39	10.7	3.65
2nd distillation	55	15.2	3.6
3rd distillation	59	17.0	3.5

Three such concentrations by distillation have been carried out with sufficient material to enable a separation to occur and in each case the final product has had approximately the same spectroscopic properties.  $E_{1\%}^{1cm}$  294  $m\mu$  ca. 55.

Ratio  $E_{1\%}^{1cm} \frac{294}{267} = 3.6-3.8$ .

As this attempt to isolate the absorbing substance was being made in the belief that it was probably the vitamin these results seemed to indicate that success might be near. The results of the biological tests were however disconcerting as the following results will illustrate.

Fraction	$E_{1\%}^{1cm}$		Ratio	Total rat dose mg.	Activity
	294 $m\mu$	267 $m\mu$			
45	30	16.6	1.8	2	+
				1	+
				0.5	+
76/2	40	10.8	3.7	3	+
				2	+
				1	+
72/c	43	11	3.9	0.5	+
				2	+
				1	?
80/3	55	15.2	3.6	2	-
				1	-
				0.5	-

Fractions 45 and 76/2 represent stages in the concentration by means of adsorption on aluminium oxide; 72/c and 80/3 further concentration by distillation. As 4-6 animals were used in the testing of each dosage these results make it impossible to retain the view that the vitamin E potency can be measured by the intensity of absorption at 294  $m\mu$ . Olcott [1934] has already cast grave doubts on the implied significance of the band because he finds (a) that the maximum is shifted by acetylation and entirely disappears after oxidation with silver nitrate without a corresponding loss of biological activity, and (b) that concentrates prepared from palm oil may show the band without being of any value as a source of the vitamin [1935].<sup>1</sup>

The possibility of loss as a result of distillation will be referred to in the discussion (p. 2520).

<sup>1</sup> Additional evidence against accepting a relation between the band and vitamin potency has recently been provided by Olcott [1935, 2]. It must be pointed out that measurements of  $E_{1\%}^{1cm}$  294  $m\mu$  alone may be misleading. We have stressed the importance of measuring  $E_{1\%}^{1cm}$  267  $m\mu$  at the same time [1935].

*Properties of vitamin E fractions.*

The most potent fractions we have prepared have been those corresponding with the highest concentration effected by adsorption on aluminium oxide of the substance showing the 294  $m\mu$  band. These preparations have evoked positive responses in vitamin E-deficient does when given in doses of 1–0.5 mg. In view of the fact that distillation at very low pressures separates such materials into two or possibly three fractions, in one of which there is a corresponding concentration of the 294  $m\mu$ -absorbing substance but in none of which has a similar concentration of the active substance been demonstrated, it is necessary to proceed with great caution in attempting to throw light on the properties of the vitamin by a study of the properties of the fractions themselves. The original investigations of Evans and Burr [1927] first indicated that the vitamin is an alcohol, and additional evidence in support of this view has since been recorded [Olcott, 1935, 2]. To it can now be added an observation made during an attempt to adsorb the vitamin directly from wheat germ oil by passing solutions in light petroleum through columns of aluminium oxide. As would be expected, the adsorbent removed uncombined sterols and hydroxylated lipochromes, amounting in all to about one-third or less of the unsaponifiable matter, but it failed to retain the vitamin. This might be interpreted as indicating that the vitamin is present as an ester in the oil.

*Hydrogenation.* We have repeatedly confirmed that vitamin E concentrates can be hydrogenated without loss of biological activity. Olcott [1934; 1935, 1, 2] has reported that hydrogenation did not fully saturate these materials. This also we can confirm, although in our experience it is possible to effect considerable reduction of the iodine value without using such drastic methods as those which he employed. By treatment with hydrogen at 3 atmospheres at room temperature in the presence of Adam's platinum oxide catalyst concentrates of vitamin E will take up hydrogen, not rapidly it is true, but steadily, so that an original iodine value of 170 or 180 falls to about 55 in 48 to 72 hours. Beyond this we have not succeeded in carrying the reduction. The time of treatment is longer than that mentioned in our earlier paper; it will be recalled that we then reported reduction to iodine values as low as 26. It has been found that the different behaviour of these preparations was due to the presence of a readily reducible component unrelated to the vitamin. The reduced compound can be separated as a white, waxy, crystalline substance and is fully saturated. Enough was not obtained to purify it satisfactorily but the crude material once recrystallised from methyl alcohol melted between 67° and 70°. This crystalline material did not separate from the more potent concentrates hydrogenated in the course of the present investigation. It is worth recording that in our experience vitamin E concentrates are highly resistant to hydrogenation when much impurity is present, particularly so when contaminated with the resinous products derived from the saponification of the original oil. Thus, for example, concentrates from unsaponifiable matter prepared industrially will often not reduce at all until freed from the dark coloured resinous contaminants, preferably by distillation.

Until there is evidence to show what proportion of these concentrates is represented by the vitamin it cannot even be assumed that a fall of iodine value on hydrogenation indicates a reduction of the active substance. The same reservation applies to Olcott's [1934] interesting observations that the vitamin will survive treatment of concentrates with chlorine and bromine and subsequent removal of the halogen by means of zinc and acid. If however these reactions

cover the vitamin itself the results indicate the presence of two reactive ethylenic groupings. Our observations of the behaviour of the vitamin in adsorption columns and Olcott's experience with oxidising reagents [1934] might also support the idea that the molecule is unsaturated to this extent. The possibility of the vitamin being of the same general chemical nature as the substance responsible for the selective adsorption at  $294 m\mu$  will be referred to later (p. 2520).

*Vitamin E in other vegetable oils.*

(a) *Cottonseed oil.* Olcott [1934] has found that crude, refined and even hydrogenated cotton-seed oils contain vitamin E in amounts sufficient to make these raw materials as satisfactory as wheat germ oil for the preparation of concentrates. This is supported by our investigation of a sample of unrefined cotton-seed oil of Brazilian origin.<sup>1</sup> From 35.3 g. of unsaponifiable matter, after removal of most of the solid sterols by freezing a methyl alcoholic solution, there were obtained as a result of two fractional adsorptions on aluminium oxide 4 g. of a concentrate of surprisingly high biological potency. Two of three rats treated with a single dose of 0.5 mg. produced normal litters.

This material was then distilled at 0.0001 mm. and gave the following fractions:

Fraction	Wt. g.	Temp. °C.	$n_D^{20}$	I.V.	$k_{1\text{cm}}^{1\%}$	
					294 $m\mu$	267 $m\mu$
77/1	0.007	50	—	—	—	—
77/2	1.16	120–140	1.4925	—	Transparent	
77/3	1.12	140–160	1.4977	94.5	47	15
77/4	1.41	160–180	1.4950	68.0	59	18

The separation of the fractions was quite sharp. The most volatile (77/1) was a minute amount of crystalline material which collected at the coolest end of the tube. Unfortunately, there was not sufficient for a test on rats, so the possibility that it was active cannot be dismissed but, on the other hand, in view of what is known of the behaviour of the vitamin on distillation it is most improbable that activity would have been shown by so volatile a compound. Fraction 77/2 was a white crystalline solid of low melting point. It crystallised from methyl alcohol fairly well at 0° but proved difficult to separate satisfactorily. The melting point was about 28°. It appeared to be an alcohol of mol. wt. about 270 giving a liquid monoacetate, but its examination is incomplete. It was spectroscopically transparent and administered to rats in doses of 2 mg. failed to prevent typical resorptions. Fractions 77/3 and 77/4 showed the 294  $m\mu$  band to a degree that encouraged us at the time to expect good potency. Doses of 1 mg. proved inactive, this being another example of unexpected loss of potency as a result of distillation. Attempts are now being made to ascertain whether reconstituting the former mixture will restore the biological activity.

The properties of fraction 77/3 were very similar to those of the corresponding fractions from wheat germ oil and they will be referred to again in the next section of this paper.

(b) *Linseed oil.* A sample of unrefined oil gave 1% unsaponifiable matter. After removal of the bulk of the sterols by recrystallisation from methyl alcohol the residue was fractionated by adsorption from light petroleum solution on aluminium oxide. The "vitamin E fraction" was inactive in rat tests in doses of 4 mg. The material was spectroscopically transparent. It may be of interest to

<sup>1</sup> We wish to thank Mr J. Hanley, F.I.C., of Messrs Bibbys Ltd., Liverpool, for this material and for other samples of vegetable oils investigated.

record that a highly unsaturated hydrocarbon of the squalene type is present in linseed oil. Good yields of an insoluble bromide were readily prepared from the fraction which was not retained by the aluminium oxide. Evans and Burr [1927] showed that flaxseed oil is not a source of vitamin E.

(c) *Sunflower seed oil*. This specimen gave about 0.6% of unsaponifiable which was fractionated in the usual manner. No biological activity was found in doses of 4 mg., nor was selective absorption at  $294m\mu$  detected.

*The substance responsible for selective absorption at  $294m\mu$ .*

Although discrepancies to which Olcott [1934; 1935, 1, 2] has drawn attention and others which are described in this paper have greatly weakened and may in some minds have entirely dispelled the view that the compound responsible for the  $294m\mu$  band is the vitamin, further investigation of its nature is of importance because frequent association with the active substance during fractionation may be significant. In our former publication the maximum intensity for this band recorded was  $E'_{1cm} 294m\mu = 49$ ; that of the minimum at  $267m\mu = 15.4$ , giving a persistence ratio of 3.18. We have since prepared material of greater intensity of absorption from cotton-seed oil and from wheat germ oil concentrates. The highest values obtained were  $E'_{1cm} 294m\mu = 59$ , with a ratio of 3.6, but we have had several specimens showing  $E'_{1cm} 50$ –56 and persistence ratios of 3.1–3.6. Much higher values for  $E'_{1cm} 294m\mu$  were often recorded for less pure material but invariably the persistence ratio was low (1.5–2.7), indicating the presence of substances showing general absorption in this region. It is of interest to compare the properties of three of the richest fractions, all of which were clear, almost colourless, rather viscid oils.

No.	$E'_{1cm}$		Ratio $\frac{E' 294}{E' 267}$	$n_D^{20}$	I.V.	$[\alpha]_D^{20}$ (benzene)	C %	H %	Mol. wt.
	$294m\mu$	$267m\mu$							
77/3	59	18	3.3	1.4977	—	+ 6.4	81.45	11.86	399
80/3	55	15	3.6	1.5000	180	+ 12.2	81.77	11.64	416
73/2	49	13.4	3.65	1.4992	178	+ 12.0	81.26	11.64	409
87/3	50	15	3.3	1.4990	172	+ 10.8	81.54	11.62	424

In all cases the fractions which had been purified by distillation condensed at a temperature range of  $130$ – $160^\circ$  at about  $0.0001$  mm. It is still uncertain whether these preparations are mixtures or whether they consist largely of one substance. One has a superficial impression that they are reasonably homogenous because there is no marked change of their properties on redistillation, partition between solvents or reabsorption on aluminium oxide. Failure to prepare crystalline derivatives has greatly hampered attempts at purification and it must again be admitted that the question of purity must be left open.

Mr F. A. Askew who has again kindly assisted us by examining these materials by the film-spreading technique has expressed the following opinion regarding fraction 80/3 and a closely related material 80/2: "If, as is probable, the concentrates contain more than one molecular species, then either (a) the two species are very similar in surface properties, or (b) if they are dissimilar they must be present in nearly constant proportions, or the proportion of one must be small, i.e. 10% or less."

A shift in the position of the maximum from  $290$  to  $281m\mu$  on acetylation was noted by Olcott [1934]. This change is sometimes obscured if other substances showing absorption in the vicinity are present but it is readily observed with the purer preparations. The new band is weaker than the original one at

294  $m\mu$  and on hydrolysis of the acetate the latter band usually reappears with somewhat diminished intensity. The hydrogenated fractions (see later) show similar behaviour. Typical figures are:

Fraction	I.V.	$E_{1\text{cm}}^{1\%}$		
		294 $m\mu$	282 $m\mu$	267 $m\mu$
80/3	180	55	—	15
Acetate 80/3	—	—	35	—
Regenerated 80/3	—	45.4	—	21.5
Reduced 80/3	55	47	—	7.8
Acetate 80/3	—	—	27.5	—
Regenerated reduced 80/3	—	42	—	18

The position of the maximum of the band does not change on hydrogenation but there is a marked increase in the persistence ratio, values as high as 6.7 having been recorded, which would be consistent with a decrease in absorption of some component in the region of 267  $m\mu$ . There is a fall both in intensity and persistence of the band when the reduced product is regenerated from its acetate by hydrolysis with hot alcoholic potash. This recalls the similar behaviour of the parent substance.

The reduced product is liquid at room temperature but can be obtained as a micro-crystalline solid by cooling a solution in methyl alcohol to  $-10^\circ$ . The melting point of the solid appears to be about  $8^\circ$ , but the small amount of material available made purification by this means difficult. Fractional sublimation at reduced pressures (0.001 mm.) was also disappointing.

Three preparations of the reduced material purified to a certain extent by one or other of these methods gave the following data:

No.	$E_{1\text{cm}}^{1\%}$ 294 $m\mu$	Persistence ratio	$[\alpha]_D^{25}$	C %	H %	Mol. wt.
R 88/2	36	6.7	—	81.3	12.71	366
R 88/3	43	6.3	+ 10.8	81.52	12.60	390
R 80/3	47	6.2	+ 12.7	81.37	12.44	398

Attempts to prepare crystalline derivatives by reaction with the hydroxyl group failed, the products proving to be in all cases either oils or soft waxy solids at room temperature. During the preparation of the 3:5-dinitrobenzoate there separated out on two occasions a small amount of a crystalline material. Only sufficient for one recrystallisation from alcohol and a melting point determination was obtained. It melted sharply at  $102^\circ$ . It was not a derivative of the substance responsible for the 294  $m\mu$  band. Hydrolysis of the oily dinitrobenzoate of the main fraction resulted in a reduction both of intensity and persistence of the band similar to but greater than that noted when the acetate was hydrolysed.

*Action of sodium in amyl alcohol.* Absorption at 294  $m\mu$  fell by nearly 80 % as a result of boiling for 3.5 hours with sodium in amyl alcohol. No reduction occurred.

*Condensation with maleic anhydride.* A preparation showing  $E_{1\text{cm}}^{1\%} = 55$  and persistence ratio 3.6 was used for this experiment. 0.48 g. was dissolved together with 0.41 maleic anhydride in 25 ml. of ether and allowed to stand in the dark for 9 days. After removal of the solvent the material was separated in the manner described by Windaus and Lüttringhaus [1931] into "neutral" and "acidic" fractions. Both were similar in appearance to the original product.

	Wt. g.	$E_{1\text{cm}}^{1\%}$	Persistence ratio
"Neutral"	0.296	40.7	2.1
"Acidic"	0.184	54.5	2.3

There is evidence that the rate of combination with maleic anhydride is slow at ordinary temperatures, for the "neutral" fraction thus obtained was further separated after a second treatment into about the same proportion of "neutral" and "acidic" fractions. The falling off in intensity and persistence of the band is attributed to the action of the hot alkali employed in the later stages of the separation.

*Colour reactions.* Various preparations showed consistent behaviour in the following reactions:

*Salkowski.* Pale straw colour darkening on standing, with development of green fluorescence.

*Liebermann-Burchard.* Gradual development of a brownish red colour with strong green fluorescence.

*Whitby B.* Straw colour.

*Benzoyl peroxide.* (Oxycholesterol reaction.) Port wine-red.

No colour was given with antimony trichloride, dimethyl sulphate or trichloroacetic acid.

*Nature of the substance responsible for the 294m $\mu$  band.*

Accepting for the time being the evidence, admittedly inadequate, that the preparations consist mainly of one compound, a few suggestions can be offered regarding its nature. The colour reactions, the behaviour during adsorption fractionations and the data from film-spreading experiments which Mr F. A. Askew has very kindly placed at our disposal<sup>1</sup> seem to point to a constitution based on a reduced polycyclic structure of the sterol type. The physical properties and those of the reduced compound indicate a fairly long side chain, branched and unsaturated. It might be isoprenic in character. On the evidence of the maleic anhydride experiment two of the ethylenic linkages are probably conjugated, and there may be a third which is less reactive. These tentative deductions are supported by the results of a preliminary investigation of the products of oxidation which will be reported later. Estimation of C-methyl by oxidation with chromic acid gave figures equivalent to a yield of 3.3 mols. of acetic acid.<sup>2</sup> Elementary analyses indicate two oxygen atoms in the molecule. One is present as a non-phenolic hydroxyl. The opinion which we formerly expressed [1935] on the basis of the spectroscopic evidence that a keto-enol grouping might be present seems no longer tenable.

## DISCUSSION.

The first point to be considered is whether the association between vitamin E activity and selective absorption with a maximum at 294m $\mu$  which has been reported by Martin *et al.* [1934] and by us [1935] can any longer be regarded as significant. Olcott [1935, 1, 2] is inclined to attach no importance to it because he has observed a disappearance of the band or a shift in the position of its maximum as a result of chemical treatment which did not appreciably reduce the biological activity, and, furthermore, he has detected the absorption band in examining

<sup>1</sup> Mr F. A. Askew has informed us that preparation 80/3 showed a limiting area at zero pressure of 67 sq. Å. The corresponding measurement for the reduced product R 80/3 was about 54–55 sq. Å. The surface potential of the reduced form is about 80–90 mv. smaller than that of the parent material. The general shape of the curves closely resembles those recorded in the paper by Askew [1935].

<sup>2</sup> Analyses by Dr Hubert Roth (Heidelberg): 6.09 and 6.43 mg. of the material required respectively 5.88 and 5.48 ml. N/100 NaOH.

concentrates from palm oil which were inactive when given to vitamin E-deficient rats. In our experience we have not encountered a case in which material giving a positive response in a rat failed to exhibit the absorption band, provided of course that a stage of purification had been reached which permitted selective absorption to be detected, but, on the other hand, we now have records of preparations which failed to exercise a biological effect such as might have been expected from the spectroscopic measurements. As we have remarked, this is noticeably true of the material which has been distilled. Evans [1932], referring to experiments made in his laboratory at pressures a good deal higher than those which we employed (0.5–0.01 mm.), comments on "considerable decomposition" observed during the distillations and points to a failure to effect by this means any great concentration of the active material. By employing much lower pressures we had hoped to prevent loss but it now appears that our distilled fractions have considerably lower biological value than was expected. There remains a possibility that the band at  $294m\mu$  is shown by the vitamin and that some changes which the molecule may undergo render it of no value to the vitamin E-deficient doe but do not materially affect the absorption. Olcott's objections make this improbable. On the other hand the gradual loss of biological potency which occurs on exposure of concentrates to ultraviolet light seems to run parallel with the photochemical decomposition of the substance absorbing at  $294m\mu$  [Drummond *et al.*, 1935]. This destruction of the vitamin must mean that it absorbs radiations in the ultraviolet unless the explanation is that it is involved in secondary reactions. Olcott has himself shown [1934] that ozone will slowly inactivate the vitamin, whilst there is a curious assortment of evidence to show that inactivation may also occur as a result of secondary reactions associated with the early phases of "oxidative rancidity" of fats [Cummings and Mattill, 1931; Evans, 1932; see also Olcott and Mattill, 1934]. A simple experiment with monochromatic irradiation in an inert atmosphere would throw valuable light on this very important matter. The most potent fractions we have obtained have effected a cure of vitamin E deficiency in female rats when given in doses of 0.5–1 mg. If the substance absorbing at  $294m\mu$  has no direct relationship with the vitamin the actual physiological dose must be much smaller. The most active material described by Evans and his colleagues produced positive tests in doses of 5 mg. [1932]<sup>1</sup> whilst that mentioned in Olcott's records is about twice as potent. A comparison of the properties of these materials with those of our most active preparations is given below.

Preparation	Rat dose mg.	C %	H %	Mol. wt.	I.V.	R.I.	Optical rotation
Evans and Burr [1927] from wheat germ oil	5	81.7	12.2	400	220	N <sup>20</sup> 1.5009	$[\alpha]_D^{20} + 7.3^\circ$
Olcott [1934] cotton- seed oil	2–3	81.6	11.5	—	90	N <sup>20</sup> 1.5090	—
Our material wheat germ oil	1.0–5	81.7	11.8	400	180	N <sup>20</sup> 1.5006	$[\alpha]_D^{20} + 8.6^\circ$

It is impossible to say how much importance can be attached to the superficial resemblance which the figures reveal, not only in so far as these three preparations are concerned but also when the comparison includes the data for

<sup>1</sup> In a footnote to this paper Evans reports that Cornish has prepared fractions from wheat germ oil which effected cures of typical vitamin E-sterility when given in doses of 1 mg. No details of the preparation and properties of this material have yet appeared, so far as we are aware.

materials of lower biological activity given on p. 2517. If the substance absorbing at  $294m\mu$  is biologically inert so far as the cure of vitamin E-deficiency is concerned we can either think that the proportion of vitamin in such materials is small, which is quite likely, or if we imagine the active substance as forming a reasonably large part of the material we can entertain the idea that it is chemically similar in character to the absorbing substance. That also is likely.

The expenses of this investigation were in part defrayed by a grant from the Medical Research Council. A contribution towards the expenses as well as a personal grant to one of us (E. S.) were provided by Messrs Imperial Chemical Industries. Considerable supplies of valuable raw material prepared from wheat germ oil were given to us by the Glaxo Laboratories. For all this generous assistance we are deeply grateful.

The authors wish to thank Mr I. L. Finar and Mr A. A. Hoover for assistance in the preparation and examination of some of the fractions referred to in this paper.

# CCCII. ASSAY OF THE GONADOTROPIC HORMONE OF PREGNANCY URINE ON MALE RATS.

By VLADIMIR KORENCHEVSKY, MARJORIE DENNISON  
AND SAMUEL LEVY SIMPSON.

*From the Lister Institute, London, S.W. 1.*

*(Received September 30th, 1935.)*

HITHERTO the assay of the gonadotropic hormones isolated from pregnancy urine or from the anterior lobe of the hypophysis has been made on immature female rats, thus measuring the female gonadotropic activity of these substances. For the unit of this activity we propose the term "female rat (or mouse) unit". It is equally important however to assay the male gonadotropic activity of these hormones, since it is clear that the results obtained from the female sexual organs cannot be applied to those of males. For the unit of this activity we propose the term "male rat (or mouse) unit".<sup>1</sup>

It is now well established that the gonadotropic hormones produce hypertrophy of the secondary sexual organs (precocious sexual maturation) in immature male animals. Several authors therefore have suggested that it might be possible to use the sexual organs of immature rodents, in particular the seminal vesicles, for the assay of gonadotropic substances.

In our previous papers, chiefly for the purpose of the assay of testicular hormones, we studied the effects of some variables on the weights of different organs in normal [Korenchevsky *et al.*, 1933; Korenchevsky and Dennison, 1934] and castrated [Korenchevsky, 1932, 1, 2; Korenchevsky and Dennison, 1934] rats. From these results we concluded that the method of assay on castrated rats, which we had previously described "could be applied to normal rats for the study of physiological or pathological conditions or for the assay of substances which influence the weight of one or more organs" [Korenchevsky *et al.*, 1933, p. 1511]. In the present paper this method has been applied to the assay of the gonadotropic hormone of pregnancy urine using the normal immature male rat as the experimental animal.

## *Technique.*

Experiments were performed on 173 rats belonging to 34 litters, the ages of which at the beginning of the injections were 22-25 days. The injections were made with a gonadotropic hormone extracted from pregnancy urine and prepared by Messrs Organon Ltd.<sup>2</sup> The strength of the preparation was given by the firm in female rat units (F.R.U.), one female rat unit being that minimum total amount of the hormone which when injected during 3 days would produce oestrus within 5 days in 50% of the injected animals.

<sup>1</sup> We suggest the following symbols for these values: "M.L.R.U." ("M.L." in order to distinguish it from the already accepted symbol "M." for "mouse") and F.R.U.; or alternatively ♂ R.U. and ♀ R.U.

<sup>2</sup> We wish to express our thanks to Messrs Organon Ltd. for kindly supplying the hormone in generous quantities and without charge.

The first 19 litters (see Tables II to IV) were each divided into a control un-injected group, usually containing two rats, and one or two injected groups each containing 2 or 3 rats, though exceptionally only one rat. The percentage changes obtained in the weight of the organs in each injected group were averaged separately for each litter. The rats of litters 20 to 26 (Exp. No. 2), 27, 31 (Exp. No. 3) and 32 to 34 (Exp. No. 4) were arranged differently, each group in these experiments containing only one litter-mate (exceptionally two) from each litter. A general average was obtained for each group and included in the Tables II to IV. Therefore, in Exp. No. 4, for example, litters 32, 33 and 34 were chosen as each contained not less than 7 rats, since 7 groups were used in this experiment.

Table I. *Secondary sexual organs in normal uninjected rats.*

Average and maximum variations of body weight and of weight (actual and per 200 g. body weight) of sexual organs of all rats and in groups A and B separately. In brackets—maximum % deviations from average figures.

32-34	68	---	74	81	83	94	98	109

This arrangement permitted a more economic distribution of the rats, when a large number of groups were required, and allowed the use of a smaller number of controls. The accuracy of the results obtained in this way was not less than that given by the litters 1 to 19.

The number of rats used in each group was as follows:

Control rats	Rats injected with daily doses of F.R.V.						
	0.5	1	2	3	4	6	10
53	16	18	24	18	15	15	14

The rats were injected subcutaneously for three consecutive days, received no injection on the fourth day and were killed on the fifth day. The daily dose was injected in two half-doses, one in the morning and the second in the evening. The changes in the weights of the secondary sexual organs (prostate, seminal vesicles and penis) were used to indicate the effects of the injections. The general details of the technique used were the same as in our previous experiments (see references at the beginning of the paper). The seminal vesicles were cut from the prostate after fixation in Bouin's fixative. A tiny bridge of tissue, holding the two lobes of the seminal vesicles together, was left uncut. It was found to be unnecessary to separate the coagulating gland from the seminal vesicles. The term "weight of seminal vesicles" in these and also in our previous papers designates the weight of the seminal vesicles together with the coagulating gland. The urethral part of the prostate was cut off at the level of the upper part of the pubic bones.

*Variations in body weight and in the weight of the organs  
of normal control uninjected rats.*

In the present assay immature rats were used within a narrow limit of age, namely, 22-25 days old. As young rats grow comparatively quickly, an investigation was made of the variations in the weights of the organs of the control rats used for the assay. The control uninjected rats were divided into two groups: A, 26 rats, 26-27 days old (final age), and B, 27 rats, 28-29 days old (final age). The results obtained are given in Table I and from these data the following conclusions may be drawn.

(1) In group B (the rats of which were only 2 days older than those of group A) the body weight and the actual weights of the sexual organs in spite of some individual variations were on the average definitely larger than those of Group A. In group B as compared with group A, the percentage increases in the body weight, seminal vesicles, prostate, prostate with seminal vesicles and penis were greater by 26, 31, 23, 24 and 15% respectively.

(2) Per unit of body weight, on the other hand, there were either no definite changes in the weights of the sexual organs or in many cases even a slight decrease.

(3) The maximum variations within each of the two groups expressed as the percentage maximum deviation from the average figures (Table I) are comparatively small, exceeding 25% only in the case of the seminal vesicles of one rat in group B for which the variation was 35%.

(4) The maximum percentage deviations from the average figure are slightly higher when all the rats are considered together, but even then do not exceed 36% except in the case of the seminal vesicles of one rat (deviation 53%).

(5) The maximum percentage deviations of the weights of the sexual organs are smaller in most cases per unit of body weight than for the actual weights, thus showing that the body weight, as well as the age of the rats influences the weight of the sexual organs of normal rats.

*The effect of injections of gonadotropic hormone.*

In order to present the data within a reasonable space we give: (a) only the actual weights of the organs of the rats in each group of each litter (Tables II to IV); and (b) the general means of percentage increases of the weights of organs (actual and calculated per unit of body weight), omitting the individual changes for each group of each litter (Table V). The general averages given in

Table V. *Influence on seminal vesicles, prostate and penis.*

The percentage increase of (A) the average actual weights of the seminal vesicles of the rats in each group of each litter and of (B) general average weight per 200 g. of body weight. In brackets—maximum % deviations from general averages in individual cases.

*Note.* The averages in the table represent the simple usual averages and they differ slightly from the statistical averages, from which the curves are constructed (see section on "Statistical description").

Table V were calculated in the usual way and are slightly different from those used for the statistical presentation of the results (Figs. 1 to 6), in which greater weight was given to the figures obtained from groups containing a larger number of rats.

In brackets, below the lines of general averages in Table V, are given the maximum percentage deviations of the individual cases from these averages. Although the weights of the organs (Tables II to IV) of the injected rats seem to show little variation, when expressed as the percentage increase (Table V) the maximum deviations from the average figures are in some cases considerable, being for the actual weights as much as 46 % for the prostate, 62 % for seminal vesicles and 87 % for the penis (excluding the small dose of 0.5 F.R.U. since this in some rats failed to produce a significant effect on the prostate). However, in spite of these individual variations, the average figures obtained give regular curves. As is shown in Tables I to V and Figs. 1 to 6, the following features are

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 5. Relation between dose of gonadotropic hormone and percentage increase in actual weight of penis.

Fig. 6. Relation between dose of gonadotropic hormone and percentage increase in weight of penis per unit of body weight.

characteristic of the effects of gonadotropic hormone on the secondary sexual organs of immature male rats.

(1) The effect on the seminal vesicles is greater than that on the prostate, and the effect on the prostate is greater than that on the penis.

(2) Flattening of the curves with the larger doses of the hormone is most pronounced in the case of the penis and least in the case of the seminal vesicles, the prostate taking an intermediate position.

*Statistical description of the curves.*

J. M. C. Scott, under the direction of Prof. H. S. Pearson, has represented the results of the assay graphically in the form of the curves given above. He writes: "Suppose some rats in a litter receive a dose  $x$  F.R.U. of the gonadotropic hormone and others are used as controls; and suppose the mean weight of a particular organ for the dosed rats exceeds the mean for the controls by  $y\%$ ; and let  $z = \frac{y}{x}$ , i.e.  $z$  represents the percentage increase in the weight of an organ per 1 F.R.U.

With these data the variation between litters in  $y$ , shows no appreciable increase with increasing  $x$ , except perhaps for  $x=10$ .

Within the range 1-6 F.R.U. the results plotted on a logarithmic scale can be represented by a straight line. This method was however not adopted because it fails for small doses. Since cubic curves did not seem quite satisfactory for large doses, another system of curves was evolved. These also contain three adjustable constants and pass through the origin, but approach a finite value for very large  $x$ . They were fitted to the data by the method of least squares. In Figs. 1-8 the average of  $y$  is plotted against  $x$ , for the actual weights or those per unit of body weight.

The data for  $x=0.5$ , 1 and 2 are consistent with the hypothesis that the response of seminal vesicles, prostate, and prostate with seminal vesicles to the hormone is linear:  $y=kx$ , or  $z=k$  ( $k$  being constant); but for  $x=3$ ,  $z$  becomes definitely smaller. Straight lines were therefore fitted to the data up to and including doses of 2 F.R.U. and the slopes  $k$  are given in Table VI.

Table VI. *Statistical summary of results of experiments (J. M. C. Scott).*

(1) Organ and basis of calculation	(2) Average $z$ (all litters receiving 0.5 to 2 F.R.U.)	(3) Probable error of $z$ if determined from Values in column 2 (average $z$ )	(4) Single litter	(5) Three litters
Prostate with seminal vesicles (actual)	27.8	$\pm 1.4$ (5.2%)*	$\pm 5.4$ (19%)	$\pm 3.1$ (11%)
Prostate with seminal vesicles (per 200 g.)	29.8	$\pm 1.3$ (4.2%)	$\pm 4.7$ (16%)	$\pm 2.7$ (9%)
Seminal vesicles (actual)	45.5	$\pm 3.1$ (6.8%)	$\pm 11.5$ (25%)	$\pm 6.6$ (15%)
Seminal vesicles (per 200 g.)	47.8	$\pm 3.1$ (6.4%)	$\pm 11.5$ (24%)	$\pm 6.6$ (14%)
Prostate (actual)	24.3	$\pm 1.3$ (5.4%)	$\pm 4.9$ (20%)	$\pm 2.8$ (12%)
Prostate (per 200 g.)	26.3	$\pm 1.2$ (4.4%)	$\pm 4.4$ (17%)	$\pm 2.5$ (10%)

\* The figures in brackets are the values of the probable error expressed as a percentage of the average  $z$  of column 2.

In Table VI the following data are given. In column 1, organ and basis for calculation; column 2, average of  $z$  for all doses not exceeding 2 F.R.U.; in column 3, probable error of the estimates given in column 2; column 4, probable error of a value of  $z$ , determined from one litter; column 5, probable error of a value of  $z$  determined from three litters.

For columns 4 and 5 a "litter" was taken as consisting of two rats, each injected with 2 F.R.U. and two control rats. In reducing Dr Korenchevsky's results, a comparison between  $m$  rats and  $n$  controls was assigned a "weight

$$\frac{m \times n}{m + n}$$

*The proposed method of assay of the gonadotropic hormones and definition of the male rat unit.*

(1) *The age of rats used for assay.* The rats in these experiments were used not earlier than the second day after weaning (22 days old) in order to allow the rats at least one day to acclimatise themselves to the change of feeding and surroundings and not older than 25 days so that the initial weights of the sexual organs used in the assay should not differ too much. It has already been shown (Table I) that when the control uninjected rats were divided into two groups (A and B), there being an average difference of 2 days between the ages of the rats of the two groups, the sexual organs of the older rats were found to be slightly heavier.

In order to ascertain if this difference influenced the results of assay in any way the hormone-injected rats used in these experiments were also divided into similar A and B groups according to age. These results are summarised in Table VII. Although the percentage increase in the weights of the organs varies in the two groups, this variation does not show a definite or constant effect of the difference in age of the two groups, nor in most cases was the variation considerable. It may therefore be concluded that a suitable choice had been made of the age (22-25 days old at the beginning of the assay), at which the immature rats were to be used for the assay experiments.

(2) *The use of the curves.* For the purpose of the assay of the minimum dose representing one rat unit the part of the curves approximating to a straight line which lies within the range 0 to 2 F.R.U. may be considered to be the most convenient, since the responses of the prostate and of the seminal vesicles are here approximately proportional to the dose of the hormone. There is little difference between the curves based on changes in the actual weights (Figs. 1, 3, 5) and those based on the changes per unit of body weight (Figs. 2, 4, 6) or between the respective maximum deviations (Table V), or the respective probable errors (Table VI). Therefore, for purposes of assay, the curves based on changes in the actual weights appear to be satisfactory and sufficiently accurate.

In order to keep within the range selected for these curves (upper limit about 2 F.R.U.), the value of the male rat unit should be represented by a percentage increase in the weight of the prostate not exceeding 50% and in that of the seminal vesicles not exceeding 90% (see Fig. 1).

At the same time, taking into consideration the fact that the maximum percentage deviations from the average may be considerable (see above), the percentage increase chosen to represent a rat unit should not be too small. It would seem that the same round figure of 40% increase in the weight of the prostate that was chosen in Korenchevsky's method of assay of testicular hormone, would be suitable for the assay of gonadotropic hormone. The corresponding increase in the weight of the seminal vesicles would be about 70% (Fig. 1), in that of the prostate weighed together with seminal vesicles 45% (Fig. 3) and in that of the penis approximately 30% (Fig. 5).

It would be necessary to work out similar curves of assay in each laboratory, since the technique of dissection of the organs, as well as the strain and breeding of the animals might be sufficiently different to affect the slopes of the curves.

Since the logarithmic curves for doses 1-6 F.R.U. approximate to straight lines, these could also be used for assay, but are not given here in order to economise space.

#### *The test.*

According to the statistical interpretation, if 3 litters of rats (containing not less than 2 animals in each group) are used for assay, the probable error of the results obtained should not exceed  $\pm 12\%$  for the prostate and  $\pm 15\%$  for the seminal vesicles. However, taking into consideration the possibility of an occasional considerable maximum deviation from the average, we would suggest the following procedure. The assay should consist of two satisfactory experiments, one preliminary and one final experiment, the former, with the help of the whole range of the curves, giving an approximate orientation of the strength of the preparation. In this preliminary experiment, say, four different doses would be injected into each litter of which there should be at least 4, each containing not less than 5 rats (otherwise more litters must be used). Such a distribution, in which one rat in each litter is left as the control and each of the remaining rats of the litter receives a different dose (as was used in the present experiment with litters 20 to 34), is to be preferred for the reasons given above. By fitting the results obtained in this preliminary experiment to the curves, a suitable dose will be found for the final experiment of the assay which is to determine the value in M.I.R.U. of the preparation assayed. This dose should fit into the part of the curves between 1 and 2 F.R.U. and for this experiment also 4 litters of rats are required. Significant discrepancies between the preliminary and final experiments and the curves will necessitate the carrying out of a third experiment.

If the results from which the curves are drawn are obtained from a large number of rats, the preliminary experiment alone will give a sufficiently accurate estimate of the strength of the preparation, provided that (a) the results of this preliminary experiment lie within the range of the curve before the occurrence of sharp flattening, and (b) the number of rats used in this preliminary experiment is sufficient.

#### *The male rat unit.*

We suggest that one male rat unit of gonadotropic hormone be that minimum total dose, which, in the injected rats, will produce on the fifth day an increase of 40% in the actual weight of the prostate and of about 70% in the weight of the seminal vesicles as compared with the average weight of the respective organs of the uninjected control litter-mates in at least 4 litters of immature males. For the injection the total rat-dose must be divided into six equal portions, one portion being injected in the morning and evening of each of 3 consecutive days, no injections being made on the fourth day. The corresponding percentage increase in weight of prostate weighed together with seminal vesicles will be about 45% and of the penis about 30%.

#### *Advantages of the method.*

The method of assay which is worked out in the present investigation and the proposed male rat unit of gonadotropic hormones present the following advantages:

(1) A measure of the male activity of the hormone can thus be ascertained.  
 (2) The curves of "dose-response" permit a comparatively easy orientation in the preliminary experiment for choosing the correct dose for the final assay experiment.

(3) In addition to the response of the prostate, which, in our opinion, is the more reliable for the definition of the rat unit, the method proposed provides a

confirmation of the results in the response of the seminal vesicles and, with a smaller degree of reliability, of the penis.

*Disadvantages of the method.*

As compared with the assay on females, the method of assay suggested necessitates a rather more complicated technique involving accurate dissection of the sexual organs, their fixation in Bouin's solution (1 day) and weighing.

*Accuracy of the method.*

Statistical investigation showed that the method was sufficiently accurate. This is further illustrated by the figures for groups A and B in Table VII. The division of the rats into the two groups A and B, though approximately halving

Table VII.

Average % increase in weight of organs obtained after injections of the hormone in rats of group A (age 26-27 days) as compared with that of group B (age 28-29 days).

the number of rats in each average, leaves the results obtained without considerable change. The values for groups A and B, especially in the case of the prostate (Table VII), differed little from the respective general averages given in Table V, especially if it is remembered that one rat unit is represented by 40 % increase in the weight of prostate and 70 % increase in that of the seminal vesicles. The ultimate proof of both the accuracy of the method and its suitability will depend upon the similarity of the results obtained in different laboratories. The accuracy of the assay made in different laboratories will be much improved when a standard preparation is available for comparison with the tested preparations.

*The comparison of the male and female rat units of gonadotropic hormones.*

We did not make a special assay on female rats. The standardisation of the hormone in F.R.U. as used by Messrs Organon was performed in their laboratories. Therefore this value of the standardisation on females is not necessarily the same as would be obtained by the somewhat different methods of assay used in other laboratories.

However, in our assay 40 % increase in weight of the prostate with a corresponding increase of 70 % in weight of the seminal vesicles, 45 % in weight of the seminal vesicles with prostate weighed together, and approximately 30 %

increase in the weight of the penis, was produced by a daily dose of 1.65 F.R.U. or a total dose of 5.0 F.R.U. (1.65 F.R.U.  $\times$  3 days). Thus a comparison of the results of our assay on males with the results of the assay on females obtained in the laboratories of Messrs Organon shows that one male rat unit of gonadotropic hormone was equal to about 5.0 female rat units.

*The comparison of the effects produced by gonadotropic hormone with those produced by androsterone and androsterone-diol.*

In our previous papers [Korenchevsky and Dennison, 1935, 1, 2; Korenchevsky *et al.*, 1935] we made an assay of fat- and water-soluble preparations of androsterone and androsterone-diol. It is not possible of course to compare the dosages and relative strengths, *i.e.* the quantitative effects of these preparations with those of gonadotropic hormone. It is however possible to compare the qualitative effects.

In the papers mentioned above we found that the chief difference between androsterone and its diol is that the former stimulates the development of the prostate to about the same or to a greater degree than that of the seminal vesicles, whilst the diol stimulates the development of the seminal vesicles much more than that of the prostate.

In Table VIII we have compared the average ratio ( $\times 100$ ) of the percentage increase in the actual weight of the prostate (1) with that of the seminal vesicles and (2) with that of the penis, after the injection of gonadotropic hormone, androsterone and androsterone-diol.

Table VIII.

Average ratio ( $\times 100$ ) of percentage increase in actual weight of prostate to that of seminal vesicles and of prostate to penis after injection of gonadotropic hormone as compared with those after injection of androsterone and androsterone-diol.

Ratio	Gonadotropic hormone	Androsterone	Androsterone-diol
1. Prostate/ seminal vesicles	54	118	64
2. Prostate/ penis	165	230	f.s. 158 w.s. 242

The effects of water-soluble (w.s.) and fat-soluble (f.s.) preparations of androsterone and the diol, as represented by the ratio prostate/sem.ves. were the same or nearly the same [Korenchevsky *et al.*, 1935, p. 2141, Table VIII], and they are, therefore, averaged in the present Table VIII.

The same similarity was observed in the ratio prostate/penis between the fat-soluble (228) and the water-soluble androsterone (232, excluding from this average as accidental the effect on the penis of the dose 7971  $\gamma$ ). A general mean of 230 was therefore tabulated in the present Table VIII. The ratio prostate/penis in the case of fat-soluble diol (158) was however different from that of water-soluble diol (242), owing to the fact that whilst the effect on the prostate of water-soluble diol was much greater than that of fat-soluble diol, the effects of these two substances were much more nearly equal in the case of the penis. These ratios are therefore given separately in Table VIII.

It is clear from the Table that qualitatively the effect of gonadotropic hormone on the secondary sexual organs is very similar to that of diol and very different from that of androsterone. In the ratio prostate/penis however the similarity is only shown between gonadotropic hormone and fat-soluble diol and not by water-soluble diol.

Gonadotropic hormone acts on the secondary sexual organs by stimulating

the testes to a normal secretion of the testicular hormones in the normal ratio. The comparison made above shows that this normal testicular endocrine activity is very similar to the effect produced on the sexual organs by the diol but not to that produced by androsterone.

This supports the statement which we made in the previous paper [Korenchevsky *et al.*, 1935, p. 2141] that the diol produces a return towards the normal ratio in the development of the secondary sexual organs, whilst androsterone fails to do so.

#### SUMMARY.

1. On the basis of experiments performed on 173 normal immature male rats belonging to 34 litters a method of assay of male activity of gonadotropic hormone preparations is suggested.

2. A regular relation has been found to exist between the dose of the gonadotropic hormone preparation isolated from pregnancy urine and the effect on the prostate, seminal vesicles and penis. This relation has been investigated statistically and represented in the form of curves.

3. In contradistinction to the female rat unit (F.R.U. or 1 R.U.) of the gonadotropic hormones, a male rat unit (M.R.U. or 5 R.U.) is suggested.

4. We suggest that one male rat unit of gonadotropic hormone be that minimum total dose which in the injected rats will produce on the fifth day an increase of 40% in the actual weight of the prostate and of about 70% in the weight of the seminal vesicles as compared with the average weight of the respective organs of the uninjected control litter-mates in at least 4 litters of immature male rats. For the injections the total rat-dose must be divided into 6 equal portions, a portion being injected on the morning and evening of each of 3 consecutive days, no injections being made on the fourth day. The rats are to be killed on the fifth day.

5. The corresponding increase in weight of prostate weighed together with seminal vesicles will be about 45% and of the penis approximately 30%.

6. One M.R.U. of the gonadotropic hormone tested was found to be equal to about 5 F.R.U. (F.R.U. being assayed in the laboratories of Messrs Organon).

7. The qualitative effect on the sexual organs of the gonadotropic hormone from pregnancy urine was found to be very similar to that of androsterone-diol and different from that of androsterone.

8. This supports our previous statement that the diol had more of the qualities of normal testicular endocrine activity than androsterone.

9. The effect of some variables and the advantages and disadvantages of the method of assay suggested are discussed.

Grants from the Medical Research Council and from the Lister Institute have enabled us to carry out this work and to them our thanks are due. We are much indebted to Prof. E. S. Pearson, to Mr J. M. C. Scott and to the Department of Applied Statistics of University College for so kindly helping us in the statistical interpretation of the results obtained.

# CCCI. THE PROLONGED TREATMENT OF MALE AND FEMALE RATS WITH ANDROSTERONE AND ITS DERIVATIVES, ALONE OR TOGETHER WITH OESTRONE.

By VLADIMIR KORENCHEVSKY, MARJORIE DENNISON  
AND SAMUEL LEVY SIMPSON.

*From the Lister Institute.*

*(Received October 1st, 1935.)*

IN this paper the results are given of the prolonged administration of androsterone and its derivatives, prepared by Prof. Ruzicka. A short communication with regard to some of them has already been made [Korenchevsky, 1935, 1, 2]. The results of our assay experiments (7 days' injection of the hormones) have been given in previous papers in this Journal [Korenchevsky and Dennison, 1935, 1, 2; Korenchevsky *et al.*, 1935, 1].

Callow and Deanesly [1935, 1, 2] studied some effects of fat-soluble androsterone and of its diol derivative on the seminal vesicles and prostate of rodents, using the method of quantitative investigation, the principle of which we are advocating. They confirmed our first experiments [Korenchevsky, 1935, 1], in which androsterone injections failed to bring about a complete return to the normal condition of the already atrophied secondary sexual organs of castrated rats ("recovery" experiments). In contrast to this result Callow and Deanesly were able to maintain ("maintenance" experiments) the seminal vesicles and prostate of castrated rats in a normal condition if the androsterone injections were started from the day of castration. They only studied this effect for 14 days however.

They also confirmed the results given from Laqueur's laboratory and the observations made by us and by some other workers [see references, Callow and Deanesly, 1935, 1, p. 1443], that there might be a significant difference between the action on rats and that on capons of some urine concentrates of the hormone of the same "capon" titre. Callow and Deanesly found the same difference between androsterone and some urine concentrates.

These and similar facts were explained by various workers by the existence of more than one sexual hormone, which fact has now been proved by the isolation of a new hormone from urine (dehydroandrosterone) by Butenandt and Dannenbaum [1934] and another from testes (testosterone) by Laqueur and his co-workers [David, 1935; David *et al.*, 1935; Laqueur *et al.*, 1935]. Ruzicka and his co-workers also continue their most important work of preparing new "artificial male sexual hormones". Among these synthetic testosterone is an important addition to their collection [Ruzicka and Wettstein, 1935]; according to Tschopp [1935, 2; Ruzicka and Wettstein, 1935] it stimulates the development of seminal vesicles and penis to a greater extent than is done by the diol (i.c.v. = about 10γ).

Callow and Deanesly [1935, 2], Tschopp [1935, 1, 2] and Laqueur *et al.* [1935] found also that the diol was more active than androsterone in its effect on the seminal vesicles. This same fact and the action on the penis and preputial glands were clearly demonstrated in our assay experiments and by the curves we gave of the action on the sexual organs of these fat-soluble and water-soluble hormone

preparations [Korenchevsky and Dennison, 1935, 1, 2; Korenchevsky *et al.*, 1935, 1]. We also showed in these papers other important points of similarity and dissimilarity between the effects of androsterone and those of the diol, estimated rat units of these substances and demonstrated a considerable difference between the rat and capon units of some preparations.

The present long-duration experiments were carried out with the following fat- (f.s.) or water-soluble (w.s.) preparations: (1) crystalline androsterone (hereinafter designated "f.s. androsterone"), (2) the lithium salt of androsterone hydrogen succinate (designated "w.s. androsterone"), (3) crystalline androsterone-diol (designated "f.s. diol"), and (4) the lithium salt of the androsterone-diol hydrogen succinate (designated "w.s. diol"). All the substances were received from Prof. Ruzicka for the investigation of their biological properties.

## MALE RATS.

### *Technique.*

Experiments were performed on 19 old normal rats belonging to 5 litters and on 112 castrated rats belonging to 20 litters, which latter were divided for 21 experiments as shown in Table I. Two or three rats of each litter were usually used in each group of the experiment.

Table I. *Effect on sexual organs of male rats.*

Average actual weights of organs of castrated rats injected with androsterone or its derivatives as compared with those of control normal litter-mates or normal rats of similar age.

No. of expts.	Preparation and daily dose injected mg.	Injections		Seminal vesicles mg.		Prostate (mg.)		Penis (mg.)		Preputial glands (mg.)		Final age days

*Note.* In Exps. 5 and 6 in brackets weight of organs of normal rats aged 123 days; in Exp. 15 in brackets a larger weight obtained in one of the litter-mates.

The general technique was the same as that described in our previous papers, with the difference that all the rats were killed by bleeding instead of by gas. For this reason we were unfortunately unable to use the values of the weights of the organs of normal rats given in our previous paper [Korenchevsky and Dennison, 1934, 1] since in that paper an investigation was made of the weights of the organs of rats killed by gas (so that blood remained in the organs). Since both normal and castrated rats were wanted in the control groups of each litter, it was possible to have both these two control groups only in the large litters. In most of the experiments therefore the weights of the organs of the normal uninjected rats were taken from the averages of the weights of the organs of rats of other litters killed at the same age. For the final ages 74, 75 and 77 days the weights of the sexual organs of normal rats were interpolated from the weights of the organs of normal rats of the nearest ages above and below these. In these cases the differences between the weights of normal organs and those of the injected rats are so large that incorrect conclusions are impossible. No normal rats of the ages 132 days (Exp. 5) and 149 days (Exp. 6) were available, so that the weights of the organs of the litters nearest in age, which were 123 days old, are given in brackets. These values in any case may be assumed to be less than those for rats 132 and 149 days old. Thus, with the exception of Exps. 5 and 6, all the values for the weights of normal seminal vesicles and prostates were calculated from the organs of normal rats of the same age.

With regard to the other organs within a period of 8–10 days there was little difference between the averages, whilst the individual differences were larger than in the case of the prostate and seminal vesicles. Therefore two general averages were calculated for the weights of the normal organs (except the seminal vesicles and prostate), one for the ages 62–70 days and one for the ages 83–91 days. The total number of normal rats used for all these averages was 57.

The hormone preparations were dissolved in the same way as in our previous experiments [Korenchevsky and Dennison, 1935, 1, 2; Korenchevsky *et al.*, 1935, 1]. The daily dose of the fat-soluble preparations was injected subcutaneously in two half-doses, one at about 10 a.m. and the second at about 5.30 p.m. the controls being injected with the same amount of pure oil; the water-soluble preparations were injected in three equal portions at about 9.30 a.m., 3 p.m. and 9.30 p.m.

The daily dose, the duration of the period of injection, the number of days after castration that the injections were started and the final age of the rats are given in Table I.

As in all our previous experiments all the organs were weighed after fixation in Bouin's fixative, except the hypophysis, which was fixed in 4% formalin-saline solution. This latter was necessary for the successful histological staining of this gland by a special modification of Mallory's method [Crooke and Korenchevsky, 1935]. After weighing, all the organs were embedded in paraffin for histological investigation, the detailed results of which will be given elsewhere.

*The effect of the male hormone preparations on  
the secondary sexual organs.*

The average data of the results of these experiments are summarised in Table I. In order to economise space the weights of the organs of the uninjected control castrated rats are not given since these have already been given in several of our previous papers. At the same time it is important to show how near it is possible

to bring the atrophied sexual organs to the normal condition by the prolonged injection of different doses of the hormone. Therefore in Table I only the weights of the organs of normal control rats or litter-mates are given.

*Maintenance experiments on males.* Androsterone was used for the injections in Exps. 1-4 in doses of 0.5 to 3.6 mg. per day (Table 1) for a period of 21 days (Exp. 3) to 47-53 days (Exps. 1, 2 and 4). The injections were begun 2-4 days after castration. A comparatively long period of injection was chosen as experiments of too short duration (7-14 days) do not show the continuance of the "maintenance" action.

As can be seen from the table, the normal average weights of the seminal vesicles at the respective ages were not attained by this means nor were even the lowest individual weights of the vesicles for the respective ages reached. With the prostate, however, after the injection of large doses (1.8-3.6 mg. per day) the weight of this organ even exceeded the average weight in Exp. 3, but not in Exp. 4, which was of much longer duration and in which the average normal weight of the prostate was not reached, though the lowest variation of 675 mg. observed for this age was exceeded even in this experiment. It is probable that the difference between Exps 3 and 4 is explained by the fact that in Exp. 3 large doses were used from the beginning of the experiment, whilst in Exp. 4, 0.9 mg. was injected for the first 26 days, 1.8 mg. for the following 19 days and 3.6 mg. for the last 8 days. The doses used failed to maintain the normal weight of the penis, whilst the preputial glands in Exps. 2 and 3 reached and even exceeded the normal averages.

*Androsterone-diols*, if used in large doses (Exps. 11 and 12, 1.46-2.93 mg. of water-soluble preparation), not only maintained the normal weight of the secondary organs but (Exp. 12) increased these by about three times the normal weight in the case of the seminal vesicles and by about twice the normal weight in the case of the prostate, though to a smaller degree in the case of the penis and preputial glands. When a dose of 0.35 mg. of f.s. diol was injected from the beginning of the experiment (Exp. 15) the normal weight of the sexual organs was maintained only in some of the injected rats. No "maintenance" experiments were made with larger doses of f.s. diol and smaller doses failed to maintain the normal weights of the sexual organs (Exps. 13 and 14).

*"Recovery" experiments on males.* Androsterone failed to cause a complete return of the seminal vesicles to the normal average weight, the highest doses used being 3.6 mg. of f.s. androsterone and 13.6-27.2 mg. of w.s. androsterone.

The recovery of the prostate occurred only in Exp. 9, in which even the normal average weight was exceeded and in Exps. 8 and 10, in which, in the rats injected with the high doses given above, the lower variation in the normal weight of the prostate was reached.

With regard to the penis the normal average weight was in no case reached, whilst that of the preputial glands became normal or even exceeded normal (Exps. 8, 9, 10).

*f.s. Diol*, when injected in daily doses of 0.7 mg. for the long period of 32 days (Exp. 18) but not when injected for only 20 days (Exp. 17) caused a return of all the sexual organs to the normal weight, the weights even slightly exceeding the normal average weight. This also occurred with the dose 5.3 mg. of the w.s. preparation (Exp. 21). With smaller doses of w.s. diol (Exps. 19 and 20), the weights of the prostate and seminal vesicles were less than the normal averages, but in Exp. 20, in which the dose was higher and the period of injection longer than in Exp. 19 (Exp. 20-27 days; Exp. 19-21 days), the weights of the seminal vesicles and prostate even exceeded the lower variation in the normal weights.

It is interesting to note that in all recovery experiments the weights of the preputial glands were greater than the normal average weights.

Unlike androsterone, the diol causes a return of all the secondary sexual organs (including seminal vesicles) to a normal condition and a normal ratio of their weights.

*The effect on the body weight, fat deposition, the endocrine and some other organs of male rats.*

In Table II a summary is given of the data referring to the organs which were found to show a change in weight.

Table II. *Influence on organs of male rats.*

Average actual weights of adrenals, hypophysis, thymus, liver, kidney and heart in the injected rats as compared with those of control castrated litter-mates or normal rats of similar age.

Organs	Group of rats	Recovery								Maintenance			
		Androsterone (mg.)					Diol (mg.)			Androst. (mg.)		Diol (mg.)

	Normal	—	—	2.00	—	1.83	2.00	2.00	1.63	2.00	—	2.29	1.66
Heart (mg.)	Castrated	815	774	671	671	—	789	671	—	789	566	969	618
	Castrated injected	868	877	848	759	684	861	830	650	858	585	1000	649
	Normal	—	—	823	—	761	823	823	761	823	—	988	708

In order to economise space, the weights of the organs of litters injected with different doses were averaged together in some cases (last 4 columns of Table), since there was little difference between the changes obtained irrespective of the dose in these cases. In this table, the weights of the organs of injected castrated rats are compared with those of uninjected castrated rats and with the average weights of those of normal rats. The dashes in the table indicate that no normal rats of the corresponding age (74, 77, 132 and 149 days old) were available (see technique).

*Adrenals.* The weights of the glands of injected castrated rats showed in all cases a considerable decrease when compared with those of uninjected castrated rats. A comparison with the normal values shows that with all doses the injections caused the hypertrophied adrenals of the castrated rats to return to the normal weight and size. If general averages are made from the figures given in

Table II and from the corresponding figures calculated per 200 g. of body weight, it will be seen that the weights of the organs of the injected rats were identical with the normal weights:

	Weights (mg.)	
	Actual	Per 200 g. body weight
Castrated uninjected rats	81	62
Castrated injected rats	51	37
Normal uninjected rats	50	38

*Hypophysis.* In contrast to the complete return to normal weight after the injection of the hormones in the case of the adrenals, only large doses of f.s. androsterone (1.8–3.6 mg.), of f.s. diol (0.7 mg.) and of w.s. preparations caused some degree of decrease in the hypertrophy of hypophysis in the majority of the rats. In three experiments however (one, in which 3.6 mg. of androsterone were injected, and two maintenance experiments in which w.s. diol was used) the weight and size of the hypophysis were reduced to the normal (or even less than normal) average figure.

Using the data in Table II and those calculated per unit of body weight, the general averages of the weights of the hypophysis for castrated, castrated injected and normal uninjected rats are 13.9, 11.7 and 9.2 mg. (actual weights); and 10.2, 8.5 and 7.1 mg. (per 200 g. of body weight) respectively.

The histological investigation of all hypophyses, which is being carried out jointly with Dr A. C. Crooke, has not yet been completed for the large doses, including those cases in which the weight of the hypophysis returned to normal.

In agreement with our preliminary communications [Korenchevsky, 1935, 1; Crooke and Korenchevsky, 1935] it is possible to say that doses lower than 1.8 mg. of androsterone produced no histological effect. However, doses larger than 1.8 mg. androsterone and 0.35 mg. of diol produced a partial return to the normal histological condition, namely a reduction in the number and size of the "signet cells", which are specific for the "castration" hypophysis. A detailed description will be given elsewhere.

*Thymus.* In castrated rats, the involution of the thymus is greatly delayed. As can be seen from Table II, the rate of involution of the thymus was increased after the injection of all doses of androsterone and diol, exceeding in most cases the normal average value for the respective age. Thus, making general averages from the data of Table II and calculating these per unit of body weight, general average weights are obtained for the weights of the thymus of castrated, castrated injected and normal uninjected rats of 556, 337 and 441 mg. (actual weights), and 411, 256 and 345 mg. (per 200 g. of body weight) respectively.

*Liver.* We have found that the liver of castrated rats is smaller than that of normal rats [Korenchevsky and Dennison, 1934, 1]. This is also clearly seen in Table II by comparing the weight of the liver in normal rats with that in castrated uninjected rats.

Injections of f.s. preparations of androsterone and diol caused a return of the weight of "castration" liver to or towards the normal weight. With w.s. preparations, however, this effect was not so clearly seen. This is due to the fact that w.s. preparations decreased the appetite of the rats thus causing a decrease in the weight of the liver, the weight of which is always influenced by the amount of food consumed. The general average weights of the livers of castrated, castrated injected and normal uninjected rats are: 9.5, 10.7 and 11.0 g. (actual weights) and 6.9, 8.0 and 8.2 g. (per 200 g. of body weight) respectively.

*Kidney.* This organ is also slightly smaller in castrated rats [Korenchevsky and Dennison, 1934, 1] which fact is seen again in the present experiments, when a comparison is made of the figures given in Table II for normal and castrated rats. As in the case of the liver, injections of androsterone or of diol restored this atrophic condition of the kidneys of castrated rats to normal (except in one litter). The general averages for the weights of the kidneys of castrated, castrated injected and normal uninjected rats were: 1.71, 1.93 and 1.95 g. (actual weights), and 1.26, 1.44 and 1.46 g. (per 200 g. of body weight) respectively.

*Heart.* There is also a slight decrease in the weight of the heart in castrated rats [Korenchevsky and Dennison, 1934, 1] which fact is confirmed by the data of the present experiments (Table II). Injections of androsterone and of diol in most cases restored the normal condition. The general averages of the weights of the hearts of castrated, castrated injected and normal uninjected rats are 733, 789 and 814 mg. (actual weights) and 548, 600 and 602 mg. (per 200 g. of body weight) respectively.

*The gain in body weight and the deposition of fat.* As compared with the uninjected control castrated litter-mates the gain in body weight was greater in the rats injected with f.s. preparations of androsterone and diol (by 11–74 %, on the average 40 %), whilst the deposition of fat did not seem to be influenced in any definite way. On the other hand, the increase in the gain in body weight was very much less with w.s. preparations (not more than 9 %) and in most cases was even less in the injected rats than in the uninjected castrated litter-mates (by 11–28 %). The deposition of fat was also less than in the control rats in most cases (by 4–49 %). These facts, as with the liver, are probably explained by the reduced appetite due to injections of the w.s. preparations in the large doses used, which seem to be toxic.

*Thyroids and spleen.* The changes in weight of these two organs were not constant. Until the histological investigation has been completed it is impossible to come to any definite conclusion with regard to the changes in the thyroid, though from our previous results [Korenchevsky and Dennison, 1934, 1] and our preliminary experiments with androsterone definite changes were expected.

*The effect on the organs of males of simultaneous injections of male and female sexual hormones.*

Experiments were performed on two litters, one containing 8 and the other 4 rats. In the first litter 2 rats were left uninjected as a control group, 3 rats were injected with androsterone alone and 3 rats were injected with androsterone and oestrone simultaneously. In the second litter 2 rats were injected with androsterone and 2 with androsterone and oestrone. The results obtained were so regular that a conclusion can be drawn. The rats were castrated at 27 days old. On the fourth day after castration daily injections with androsterone were started and three times a week oestrone was injected into those rats receiving both hormones. The injections were continued for 47 days and the rats were killed at 77 days old. The changes obtained in this "maintenance" experiment are summarised in Table III.

It can be seen from the table, that in the rats injected simultaneously with both hormones (1) the prostate and the seminal vesicles were much larger than in those injected with androsterone alone; (2) the percentage increase in the prostate was nearly equal to (Exp. 2) or larger than (Exp. 1) that of the seminal vesicles and (3) with the smaller dose of androsterone the stimulating action of oestrone was much more pronounced. This last effect may be explained by the fact that an increase in the dose of androsterone has a much greater stimulating

Table III. *Effect on actual weight of organs of simultaneous injection of androsterone and oestrone on male rats.*

Organs	Groups injected with:	Average weight of organs (mg.)		% change in weight of organs	
		Exp. 1	Exp. 2	Exp. 1	Exp. 2
Seminal vesicles	Androsterone	39	64	—	—
	Androsterone + oestrone	68	87	{ + 74 { (+ 106)	{ + 36 { (+ 57)
Prostate	Androsterone	237	452	—	—
	Androsterone + oestrone	517	637	{ + 118 { (+ 164)	{ + 41 { (+ 62)
Adrenals	Androsterone	48	41	—	—
	Androsterone + oestrone	65	55	{ + 35 { (+ 72)	{ + 36 { (+ 55)
Hypophysis	Androsterone	13.8	12.1	—	—
	Androsterone + oestrone	15.0	14.7	{ + 9 { (+ 29)	{ + 21 { (+ 39)
Thymus	Androsterone	745	465	—	—
	Androsterone + oestrone	527	363	{ - 29 { (- 16)	{ - 22 { (- 12)
Gain in body weight	Androsterone	183	188	—	—
	Androsterone + oestrone	143	156	- 22	- 17

*Note.* In Exp. 1 the hormones were injected in the daily doses: androsterone 0.5 mg., oestrone 60 i.u.; in Exp. 2, androsterone 1 mg., oestrone 60 i.u. In brackets percentage change in weight of organs per unit of body weight.

effect on the sexual organs than the simultaneous administration of oestrone. This is shown even in recovery Exps. 8 and 9 (Table I), in which large doses of androsterone after only 17–21 days' injection brought about an increase in the weight of the prostate about equal (Exp. 8) to that obtained in Exp. 2, Table III or above the normal weight (Exp. 9, Table I). By increasing the dose of androsterone in Exps. 8 and 9 much larger seminal vesicles also were obtained (250–300 mg.) than by addition of oestrone to androsterone in Exps. 1 and 2, Table III (68 and 87 mg.). The addition of oestrone to androsterone caused an increase in the weight of the adrenals, a slight increase in the weight of the hypophysis and a decrease in the weight of the thymus and the gain in body weight. The deposition of fat decreased slightly (by 26 % in one litter and by 8 % in the other). The changes in the adrenals and hypophysis and the gain in body weight must be considered pathological.

No considerable or constant changes were noted in the weights of the penis, preputial glands, thyroid, liver, kidneys, spleen or heart.

A striking difference is seen on comparing the results obtained in these experiments with those previously published [Korenchevsky and Dennison, 1934, 2] on the simultaneous injection of oestrone and testicular hormone preparations from urine. Whilst in the present experiments the effect of the addition of oestrone to androsterone was more marked in its action on the prostate, the addition of oestrone to the urinary hormone preparations had much more effect on the seminal vesicles than on the prostate. This is probably connected with the weaker reaction to androsterone shown by the seminal vesicles as compared with the much stronger reaction of the prostate. Points of similarity in the previous and present results are the decrease in the gain in body weight, the slight decrease in the deposition of fat, the stimulation of the rate of involution of the thymus and the slight increase in the weight of the adrenals and hypophysis (though the adrenals were slightly increased only in the experiments with the

urinary preparation "H" [Korenchevsky and Dennison, 1934, 2, Table V, p. 1491].

The variation in the "hypertrophic" effect of oestrone on the adrenals of castrated rats probably depends on the degree of conversion of the adrenals by castration into "castration" adrenals. As we have already shown [Korenchevsky and Dennison, 1935, 3] the effect of oestrone on the adrenals of normal rats is similar to, if not identical with that observed after castration. Therefore if castration has already produced the maximum effect on the adrenals, oestrone should have no further effect; but if the conversion of the adrenals by castration is not complete, the injection of oestrone will finish this change.

*Does testicular hormone possess a so-called "rejuvenating" influence?*

Androsterone was injected for 24 days into 12 approximately year-old normal male rats belonging to 5 litters, 7 litter-mates being left as the controls. These rats had already become lazy and obese with unclean fur and skin, not cleaning themselves properly from insects, and had lost the agility, restlessness and curiosity typical of healthy young and adult rats, whilst some had in addition chronic pneumonia which was revealed on dissection. Observation during life and examination of the organs after killing showed that androsterone in doses of 0.1 or 0.9 mg. had no favourable effect on these old injected rats as compared with their control uninjected litter-mates.

The changes obtained in the weights of the organs, the fat deposition and body weight were small and were not constant. The testes in most of the injected rats were on the average about 10 % smaller. The results obtained were therefore similar to those previously obtained on normal adult rats injected with purified testicular hormone prepared from urine [Korenchevsky *et al.*, 1933].

*The relation between the dose of androsterone and the effect on the sexual organs.*

The number of experiments available is too small for drawing a definite curve. Moreover, the ages of the rats injected and the period of time after castration that the injections were started differed. However, for comparison Exps. 5, 6, 7 and 9 were chosen, since in these androsterone was injected for about the same period (21 or 22 days). From Table IV it can be seen that there

Table IV. *Relation between the dose of androsterone and percentage increase in weight (actual and per unit of body weight) of sexual organs of castrated male rats.*

Androsterone (mg.)	% increase in weight of organs							
	Seminal vesicles		Prostate		Penis		Preputial glands	
	Actual	Per unit of body weight	Actual	Per unit of body weight	Actual	Per unit of body weight	Actual	Per unit of body weight
0.45	228	221	222	223	106	130	114	116
0.9	404	403	476	506	124	111	166	179
1.8	461	400	800	724	204	183	181	160
3.6	1823	2060	1598	1887	226	281	163	214

appears to be a direct proportional relationship between the dose and the percentage increase in the case of the prostate, which is in agreement with our assay experiments [Korenchevsky and Dennison, 1935, 1]. Whilst the seminal vesicles show this same proportional relationship with the two smaller doses of 0.45 and 0.9 mg. and the highest dose of 3.6 mg., a lag occurred with the middle

dose of 1.8 mg. which produced an effect equal only to the half dose of 0.9 mg. We draw attention to this fact, since we found a similar flattening of the curve of seminal vesicles with the middle dose in our assay experiments of 7 days' duration [see Korenchevsky and Dennison, 1935, 1; Table VI, p. 1726].

The same approximate direct proportion between the dose and the effect is also seen (Table I) in the present Exp. 1 (0.5 mg. androsterone) and Exp. 2 (1.0 mg. androsterone). Injections were made for 47 days and the following percentage increases in the weights of the organs were obtained:

Androsterone (mg.)	Seminal vesicles		Prostate	
	Actual	Per 200 g.	Actual	Per 200 g.
0.5	179	175	248	234
1.0	357	309	565	500

## FEMALE RATS.

*Technique.*

Injection experiments were performed on 18 litters containing 103 spayed rats and the effects of ovariectomy were studied in 4 litters containing 19 rats. Ovariectomy was performed at ages varying from 23 to 27 days, *i.e.* before sexual maturity. The number of rats used in each experiment, the final age, the number of days after ovariectomy that the injections were started and the period of injection in days are given in the last 4 lines of Tables V and VI. The dose of the hormone injected is given in the top line.

Table V. *Effect of sexual hormones on female rats.*

Average actual weights of organs of control rats and their litter-mates, injected with f.s. or w.s. preparations of androsterone, androsterone-diol and oestrone.

Organ	Group	Androsterone (mg.)			Diol (mg.)				Oestrone (i.u.)

The technique of the experiments and the preparations of the hormones injected were the same as those used in the experiments on male rats.

The weights of the organs of normal female rats were not investigated. In two litters only, 2 litter-mates of each litter were kept as normal controls. In the tables therefore control rats mean uninjected spayed rats as compared with injected spayed rats.

In normal female rats the condition of several organs changes to some extent with the sexual cycle. It would therefore be necessary to make a preliminary detailed investigation of the effect of the sexual cycle on the weight of the organs of normal female rats, before experimenting on normal females.

#### *Female preputial glands.*

Under the skin at the exit of the urethra of the female rat are situated two flat club-shaped glands, which in their form and histological structure are homologues of the preputial glands of the male. We were unable to find a description of these glands in the previous literature and we have therefore named them "female preputial glands".

A detailed histological description will be given elsewhere.

*The effects of ovariectomy.*

For the reason just given we shall mention only briefly some definite results, which we obtained in experiments on 4 litters of females containing 19 rats, in which half the rats in each litter were spayed, the other half being left normal.

The litters were killed 33–88 days after ovariectomy at ages varying from 63 to 114 days. That the sexual organs atrophy after ovariectomy is already well known. In our rats the respective average percentage decreases in the weights of the uterus and of the vagina were 87 and 55 % (actual weights) and 89 and 56 % (per unit of body weight) as compared with those of their normal litter-mates. The female preputial glands which are homologous with the preputial glands of the male, were smaller in most rats by about 20–40 %. However, as in the case of the male glands, the individual weights of the female glands vary considerably. The involution of the thymus was delayed, so that in ovariectomised rats this organ was heavier than in the normal litter-mates (by about 40–70 %). The deposition of fat was increased in most of the rats (by about 24–77 %). Changes in the other organs were small.

*The effect of sexual hormones on the organs of spayed females.*

In the following series of experiments only one of the hormones (male or female) was injected into any rat. The results are summarised in Table V, in which, in order to economise space, only the actual weights of the organs are given and mention will be made of those cases, in which the percentage changes per unit of body weight differ considerably from these.

*The sexual organs.* Oestrone as is well known and as is shown in our experiments (Table V) causes a considerable return to the normal condition of the atrophied uterus and vagina. Our experiments showed that the female preputial glands remain unaffected or were even slightly decreased.

Whilst androsterone was found to have no considerable effect on the uterus and vagina, it caused a considerable hypertrophy of the preputial glands.

Diol, especially in the larger doses, had a considerable stimulating effect on all the sexual organs of spayed rats, uterus, vagina and preputial glands. With the largest dose (3.54 mg. w.s. diol, Table V) the effect approached that of oestrone, the condition of the sexual organs however being far from normal as is shown by the following average figures for the weights (mg.) of the uterus and vagina in one litter of rats:

	Uterus	Vagina
Normal uninjected rats	355	233
Spayed uninjected	33	81
Spayed injected with diol	123	172
Spayed injected with oestrone	155	146

In addition in some of the rats injected with diol a "female prostate" developed from the microscopic rudimentary periurethral glands. This reaction has already been mentioned [Korenchevsky, 1935, 2] and will be described in detail elsewhere.

*Adrenals.* Whilst the effect of oestrone on adrenals of spayed rats was slight or negligible, both androsterone and the diol caused a considerable, sometimes a very considerable decrease in the weight of these organs. Thus the effect of the male hormone on the weight of the adrenals was the same in both castrated males and spayed females.

*Hypophysis.* Whilst oestrone had no effect on the weight of the hypophysis of spayed females, large doses of androsterone and diol were followed by a decrease in the weight of this organ.

*Thymus.* It is well known that involution of the thymus is delayed in spayed rats. The figures in Table V show that the female and male hormones caused a return to normal in the speed of involution of the thymus to about the same degree.

*Liver and kidneys.* The effects of androsterone and diol on the liver and kidneys of spayed females were similar to those observed on these organs in the case of castrated males. There was a definite increase both in the actual weight and in the weight per unit of body weight except with the highest dose of w.s. diol (3.54 mg. per day) with which dose the appetite decreased. As has already been mentioned, loss of appetite with this dose was also observed in males and resulted in a smaller liver weight. These increases in weight of liver and kidneys did not occur with oestrone injections, after which in the majority of rats the actual weight of the liver decreased, though this was less noticeable or even absent when the weights were calculated per unit of body weight. This is probably explained by the lower body weight of the oestrone-injected rats.

*The gain in body weight and in the deposition of fat.* The gain in body weight and the deposition of fat were increased slightly by the injection of androsterone and of small doses of diol. Large doses of diol did not improve the gain in weight (Table V) and with the largest doses there was even a small decrease in the gain in weight. The deposition of fat was decreased, on the average by about 50 % by the use of large doses of f.s. and w.s. diol.

Oestrone, in the doses used, in all cases slightly decreased the gain in body weight (Table V) and the deposition of fat (by about 17 %).

Thus, speaking generally, small doses of male hormones had a favourable effect, whilst large doses and oestrone injections had a depressing effect on the nutrition of female rats as far as can be judged from their gain in weight and fat deposition.

*The effect on females of the addition of male hormones to oestrone injections.*

This is an important question, since it is now established that both "male" and "female" hormones are normally excreted in the urine, probably in normal circumstances in a definite ratio.

The experiments for the elucidation of this question are summarised in Table VI, in which the following data are given: the weights of the organs in which changes were found, the number of rats used in the experiments, the age of rats, the number of days after spaying that the injections were started and the period of the injections.

The control rats in these experiments were oestrone-injected spayed females, i.e. rats already supplemented by the female hormone which might be expected to bring about a complete recovery of the spayed rats to the normal condition. These rats were compared with their litter-mates injected with the same dose of oestrone with the addition of androsterone or diol.

*The sexual organs.* If there were any doubt as to the male hormones alone having a stimulating effect on the sexual organs of spayed rats, the experiments on the simultaneous administration of these hormones with oestrone proves conclusively their co-operative effect.

It can be seen from the respective figures of Table VI that the addition of androsterone or diol increases the "recovery" effect of oestrone seen in the uterus. The largest doses of androsterone and diol increased this effect of oestrone by about 60 and 130 % respectively and in the case of the vagina increased the effect by about 40 and 60 % respectively. Thus the addition of male hormones to

oestrone produced a considerably larger effect on the uterus and vagina of spayed rats than is obtained by the use of either male or female hormone alone.

Both in the experiments which have already been mentioned (Table V) and in the experiments summarised in Table VI the female preputial glands of the rats injected with oestrone alone were small, varying on the average from 50 to 68 mg. This shows once more that oestrone has no effect on these glands. The addition of male hormone to oestrone injections increased the weight of these glands up to 275 mg. (Table VI) which weight can be obtained for these glands by the injection of androsterone or diol alone (Table V).

Therefore the addition of androsterone or of diol to oestrone injections was followed by the co-operation of these hormones in bringing about an improvement in the recovery to the normal weight in the case of the atrophied uterus and to a smaller degree of the atrophied vagina of spayed rats.

On the other hand this co-operation was absent in the case of the female preputial glands, for the greatest development of which the male and not the female hormones are responsible.

*Thymus.* Oestrone slightly increases the rate of involution of the thymus in spayed rats (Table V). Therefore the weights of the thymus in the rats injected with oestrone alone (Table VI) are smaller than those given for this organ in un-injected spayed rats (Table V). By the addition of androsterone or of diol to oestrone in most cases the rate of this process of involution of the thymus, already stimulated by oestrone, was still further increased (Table VI). Therefore there appears also to be a co-operative action between androsterone and oestrone in the case of the action on the thymus, which is however much less than in the case of the uterus.

*Adrenals.* Not only was it seen that there was no "co-operative" action in the case of the adrenals, but in some cases oestrone appeared to have an antagonistic effect on the action of the male hormones. The following experiment on 6 spayed litter-mates may be given as an example. The actual weights of the adrenals of 2 rats injected with oestrone alone were 87 and 77 mg.; of 2 injected with androsterone 42 and 51 mg.; and of 2 injected with the same dose of androsterone and oestrone 70 and 73 mg. However, the typical effect (*i.e.* reduction of weight) of androsterone on the adrenals of spayed rats (although probably decreased) was still seen in all the experiments, in which male and female hormones were injected simultaneously (Table VI).

*Hypophysis, liver and kidneys.* In all these organs the typical action of androsterone or diol was obtained in most cases (Table VI), but, since the effect was no greater than that obtained by the injection of the male hormone alone, oestrone had no co-operative effect.

*The gain in body weight and the deposition of fat.* In the same way the beneficial stimulating effects of moderate doses of androsterone and of diol on the gain in body weight and on the deposition of fat predominated over the depressing effect of oestrone. The data in Table VI show this in the case of the gain in body weight. The fat deposition, which decreased slightly in most oestrone-injected rats (on the average by about 17 %), increased as compared with these rats (on the average by about 55 %) in rats injected simultaneously with oestrone and androsterone or diol. The following experiment on 6 spayed litter-mates will serve as an illustration. The actual weight and the weight per unit of body weight of the retroperitoneal fat were respectively in:

	g.	g.
2 oestrone-injected rats	3.1	2.8
2 androsterone-injected rats	4.5	5.2
2 androsterone- and oestrone-injected rats	6.8	4.6

## DISCUSSION.

Before the histological investigation has been completed, we cannot say how far the changes obtained in the weights of the organs after the injections represent a true normal recovery.

*The difference between the effects of fat-soluble and water-soluble preparations.*

In general, it can be said that no important differences in specific action were found between fat-soluble and water-soluble preparations of the male hormones. The large doses of water-soluble preparations used in our experiments, however, had a slightly toxic effect, depressing the appetite, the gain in body weight, the deposition of fat and the stimulating action on the liver.

*The difference between the effects of androsterone and diol preparations.*

In *males* the most important difference lies in the difference in the actions on the sexual organs. Whilst androsterone, even in the largest doses used, was only able to bring about complete recovery to the normal condition in the case of the prostate and preputial glands, diol caused a complete return to the normal weight, in some cases even exceeding this, in the case of all the sexual organs. In Exp. 12 (Table I) this overstimulation by diol of the prostate and seminal vesicles reached a remarkably high degree and overstimulation of the preputial glands was seen in about half of the experiments.

In our previous papers [Korenchevsky and Dennison, 1935, 2; Korenchevsky *et al.*, 1935, 1, 2] from the results of 7-day experiments and from the comparison of the action of diol on the sexual organs of castrated male rats with that of gonadotropic hormone on the sex organs of immature male rats, we came to the conclusion that diol and not androsterone appeared to have the properties of a complete male sex hormone. How complete are these properties however it is impossible to say before completing the histological investigation and carrying out metabolism experiments. In addition it is necessary here to emphasise that diol has not yet been shown to be present either in the organism or in the urine, nor quantitatively is it so effective as testosterone.

In *females* it was also found that the stimulating action of diol was stronger than that of androsterone in the case of the recovery of the atrophic uterus and vagina. We did not find any other significant differences between these two substances.

*The co-operative and antagonistic actions of male and female hormones.*

We propose to use the term "co-operative action" in those cases where the action on some organs or functions of two or more substances (whether hormones or not) is greater when they are administered simultaneously than when they are used separately.

In our previous experiments with urinary concentrates of the hormone [Korenchevsky and Dennison, 1934, 2] and in the present experiments with androsterone a co-operative effect of male and female hormones on the reaction of the sexual organs (and to a less degree of the thymus) was seen in *males*.

The addition of oestrone to urinary hormone preparations, however, causes a much greater stimulation of the seminal vesicles than of the prostate, whilst, when androsterone is used with oestrone, the degree of stimulation of the seminal vesicles is less than or equal to that of the prostate. This fact also indicates that in the urinary concentrates of the male sexual hormone besides androsterone another male hormone is present.

This co-operative action was also seen in *females* in the effect on the female sexual organs (and to a smaller degree on the thymus) of androsterone or diol used with oestrone.

The *antagonistic effect* was not so clear as the co-operative effect, but was seen to some extent in two cases, in the action on the adrenals and on the gain in body weight. The addition of oestrone to androsterone was followed by a lessening of the action of androsterone in (1) decreasing the hypertrophied adrenals to the normal weight; and (2) in increasing the gain in body weight in castrated males and spayed females.

*The importance of the co-operative action in the recovery to the normal condition of the sexual organs of castrated and spayed rats.*

We have found that in *males* an increase in the dose of androsterone or of diol always gave a quicker and greater recovery of the sexual organs of castrated rats than was given by the addition of oestrone. The co-operative action in males therefore seems to be of little importance, since it is replaceable.

With *females* however this does not seem to be the case, though this conclusion was based on only one experiment of 7 litter-mates (final age 62 days; period of injection 28 days), since normal controls were present only in this litter. However the regularity of the results obtained in the individual rats of the groups and the clear-cut results between the groups are convincing as is shown below by the average weights of the sexual organs in the groups:

	Uterus (mg.)		Vagina (mg.)		Female preputial glands (mg.)	
	Actual	Per 200 g. body weight	Actual	Per 200 g. body weight	Actual	Per 200 g. body weight
2 normal litter-mates	277	335	229	279	94	118
2 spayed injected 180 i.u. oestrone	128	155	171	206	50	60
3 spayed injected 180 i.u. oestrone + 0.35 mg. diol	300	343	214	241	150	169

It follows from these figures that a large dose of oestrone injected alone failed to bring about a complete return of the sexual organs of spayed females to the normal condition, whilst complete recovery was obtained by the addition of diol.

The degree of change obtained in the other experiments given in Tables V and VI also suggests that the co-operative action of male and female hormones is important for the recovery of the sexual organs of spayed females to the normal condition. In contradiction to this is the fact that very large doses of androsterone (the hormone found in the organism) are required to produce this effect and even then the reaction is much less than that obtained with diol (the artificial hormone not found in the organism). There is reason however to expect that the action of testosterone on females will probably be similar to that of diol, since the effects of these substances on males are in many respects similar.

#### *Pathological effects.*

The female preputial glands in females are homologous with the preputial glands in males. Whilst oestrone appears to have no effect on either of these glands, both androsterone and diol cause their overstimulation beyond the "age-weight in" both cases. It seems that the overstimulation of the female preputial glands and the development of the "female prostate" are both abnormal features

produced in spayed females by large doses of male hormones. Simultaneous administration of oestrone failed to counteract this abnormal effect of the male hormones. These abnormal actions of the male hormones must be regarded as being relatively unimportant since they have no harmful effect on the organism as compared with the dangerous action of oestrone on some of the organs in males [Lacassague, 1933; Burrows and Kennaway, 1934; Korenchevsky and Dennison, 1935, 3].

*The manifold effects of the sexual hormones.*

In our previous papers [Korenchevsky *et al.*, 1933; Korenchevsky and Dennison, 1934, 1; 1935, 4] we demonstrated the manifold effects of castration in male rats and the reversal by purified male hormone preparations prepared from urine of most of the changes produced.

The present experiments with pure androsterone and its derivatives confirm the manifold effects which, in addition to those on the sexual organs, are seen in the changes in gain in body weight, deposition of fat, adrenals, thymus, liver, kidneys and heart.

We wish particularly to emphasise the stimulating effect of these hormones on the heart, liver and kidney, with regard to the clinical possibilities. If this effect should also be found in human beings, the male hormones may become a valuable acquisition in the treatment of suitable diseases in male patients, since these hormones are natural stimulants and seem to be mild but effective in action. We therefore suggest that a clinical trial of these substances should be made in suitable diseases, since no harmful results can be expected to follow their application, whilst the advantages may be considerable.

SUMMARY.

1. Experiments were performed on 188 normal and castrated male rats and 122 normal and ovariectomised female rats in order to study the effects of the prolonged administration of Ruzicka's artificially prepared androsterone and its fat- and water-soluble derivatives, injected alone or simultaneously with oestrone.

2. *Castrated male rats.* From the comparison of the results of the previous short-duration experiments on these substances, the present long-duration experiments and our previous experiments with the gonadotropic hormone of pregnancy urine, diol was found to have the qualitative properties of a true male hormone: the secondary sexual organs (including the seminal vesicles) of castrated males were maintained (by suitable doses) in a normal condition or even reached more than the normal weight and the atrophied organs were restored to the normal weight.

3. Androsterone (even in the largest daily dose used of 3.6 mg.) had not all these properties, being mainly deficient in restoring the atrophied seminal vesicles and penis in castrated males, though prostates and preputial glands of normal or more than normal weight were obtained in both maintenance and recovery experiments.

4. The injection of very large doses of water-soluble androsterone (about 13.6–27.2 mg. per day) and water-soluble diol (about 2.9–5.3 mg. per day) had a depressing effect on the gain in body weight, the deposition of fat and the stimulation of the liver.

5. The effects of androsterone and diol and their water-soluble esters were manifold, for not only were the sexual organs of castrated rats restored to or

towards the normal condition, but also the following organs or functions: gain in body weight, adrenals, hypophysis (with large doses), thymus, liver, kidneys and heart.

6. A co-operative action on the seminal vesicles and prostate (and to a smaller degree on the thymus) was seen between androsterone and oestrone, though a quicker and greater effect could be obtained by increasing the dose of the male hormone preparations. An antagonistic action on the adrenals appeared to occur between the male hormones and oestrone.

7. In the present experiments of long duration, as in the previous experiments of short duration, a direct proportional relationship was found within the range observed between dose and effect on the prostate and seminal vesicles (with an apparent lag however in the effect on the seminal vesicles with the middle dose used).

8. *Normal male rats.* No "rejuvenating" or other favourable effect on old male rats was seen with the doses used.

9. *Female rats.* A description was given of the "female preputial glands", homologues of the preputial glands of the male rat.

10. *Ovariectomised female rats.* The injection of large doses of diol caused a partial recovery of the atrophied uterus and vagina of ovariectomised females. This effect was slight even with large doses of androsterone.

11. These injections also caused a hypertrophy of the female preputial glands to a weight which was above the normal for the respective age and in some rats the development of a "female prostate" from the rudimentary periurethral glands.

12. Large doses of diol depressed the appetite and gain in body weight, whilst with medium and small doses and with fat-soluble androsterone these were improved. The injection of androsterone and of diol also increased the rate of involution of the thymus, decreased the weight of the adrenals and (with large doses) of the hypophysis and slightly increased the weights of the kidneys and liver, thus in general producing results similar to those obtained in castrated male rats.

13. In ovariectomised female rats injections of oestrone brought about a return towards the normal weight of the atrophied uterus and vagina, increased the speed of involution of the thymus and decreased the deposition of fat and the gain in body weight, but seemed to have no effect on the weight of the adrenals. In most cases there was a slight decrease in the weights of the liver and kidneys.

14. Simultaneous injections of oestrone and large doses of androsterone or diol showed a "co-operative recovery effect" on the weights of the uterus and vagina and to a smaller degree on the thymus, whilst there seemed to be a slightly antagonistic effect between the actions of oestrone and the male hormones on the adrenals.

Grants from the Medical Research Council and from the Lister Institute have enabled us to carry out this work and to them our thanks are due. We would also like to express our deep gratitude to Dr A. Girard for kindly supplying us with oestrone.

# CCCIV. THE RELATION OF MICRO-ORGANISMS TO CAROTENOIDS AND VITAMIN A.

## II. THE PRODUCTION OF CAROTENOIDS BY *MYCOBACTERIUM PHLEI*.<sup>1</sup>

BY MARY A. INGRAHAM AND HARRY STEENBOCK.

*From the Department of Agricultural Chemistry, University of  
Wisconsin, Madison.*

*(Received August 26th, 1935.)*

ALTHOUGH great advances have been made in our knowledge of the chemistry of the carotenoid pigments little is known concerning the physiology of their production or their rôle in living cells. Ingraham and Baumann [1934] reported that many bacteria were capable of synthesising carotene when grown on simple media in the dark. Since that time a more detailed study has been made of the production of carotene and associated pigments by one of these organisms. *M. phlei* was selected because it grows well on a variety of synthetic media and because its chemical composition and physiological reactions have received more than ordinary attention.

Many factors were found to affect the pigment content of *M. phlei*. This made it advisable to define arbitrarily a set of standard conditions and then to compare the growth and pigmentation obtained in various experiments with those observed under these standard conditions. The medium used contained per litre of distilled water: asparagine 5.0 g., glucose 50.0 g.,  $K_2HPO_4$  1.0 g.,  $MgSO_4 \cdot 7H_2O$  1.0 g., Na citrate 0.5 g., Fe citrate 0.05 g. It was bottled in 25 ml. amounts in 6 oz. signet bottles which were then capped and autoclaved. Cultures of 5-day cells grown under standard conditions were used as the inoculum. The temperature of incubation was 37°. Our first observations were made on the gross pigmentation produced when the carbon source, the nitrogen source, the mineral salts, the temperature of incubation and a number of other factors were modified. In later studies we also concerned ourselves with the nature of the different pigments produced.

The cells were collected on filter-paper, washed with distilled water and dried in thin layers at 37° for 48 hours. This procedure did not result in any appreciable loss of pigments. The weighed dried cells were treated with hot 95% alcohol and the extracted pigments were then estimated quantitatively with a Lovibond tintometer. The hydrogen ion concentration of the medium was determined colorimetrically. The Shaffer-Hartmann method was used in following the rate of utilisation of glucose. The nitrogen in the medium was determined by the Kjeldahl method. Lipoids were roughly estimated by weighing the ether-soluble portion of an absolute alcohol extract of dried cells.

Growth under standard conditions has been quantitatively reproducible over a period of two years. Typical curves for the cell weight and total pigment production are given in Fig. 1. The weight of cellular material increased rapidly to a maximum at 9 days and then autolytic processes set in. Pigmentation

<sup>1</sup> Published with the permission of the Director of the Wisconsin Agricultural Experiment Station.

increased during the growth period and continued to increase long after autolytic processes had been initiated. Glucose was found to disappear from the medium at about the 9th day. At the end of 6 days 95% of the asparagine-N had been absorbed by the cells. It was therefore not surprising to find that the increase in cell weight from the 6th to the 9th day was largely due to the production of lipoids which were quickly destroyed when the sugar was exhausted.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

When yellow cells instead of white cells were used as the inoculum the growth was again only slightly pigmented until the second and third weeks, and the question therefore arose as to whether the progressive yellowing was an invariable consequence of age. This was found not to be the case, for when cultures which had been stunted by lowering the concentration of glucose to 2% were allowed to age, the cells remained white (Fig. 2). On the other hand when the glucose concentration was raised to 10% the old cells became very yellow (Fig. 3). In these experiments the pigment content of the cells varied directly with the amount of growth rather than with the age of the culture. However, when the amount of growth was varied independently of the concentration of sugar by changing the volume of medium used in each bottle, it was found that pigmentation was not affected. Therefore the thickness of the pellicle and the amount of growth per bottle were not determining factors in the pigmentation of the organism.

The possibilities existed that there was present in the fresh medium some substance inimical to pigment production which was removed as the cells grew,

or that some substance was produced by continued growth which stimulated pigment production. Evidence in favour of the former concept was obtained from an experiment in which cells were grown in a medium containing every constituent of the standard medium in double strength. With large inocula excellent growth was secured but the maximum pigmentation per g. of cells remained slightly lower than on the standard medium and very much lower than in a control series in which only the concentration of the glucose had been doubled. The specific factors involved will be discussed later.

The substitution of glycerol for glucose in the standard medium brought about striking changes in the growth and pigmentation of *M. phlei*. The rate of growth (Fig. 5) was considerably slower on glycerol than on glucose and the

Fig. 5.

maximum cell weight per 100 ml. of medium was very much less. However, the cells grown on glycerol became yellow early in the growth period and their pigment content during the later stages was many times that obtained on glucose. This is particularly interesting in view of the close chemical relationship between glycerol and glucose as contrasted with the carotenoid pigments. There is a possibility that some glycerol may be formed as an intermediate in the breakdown of glucose, but unfortunately little is known concerning the steps in the utilisation of either of these compounds by *M. phlei*. That glycerol might serve as a precursor of the carotenoid pigments in one way or another was further indicated by the fact that additions of small amounts of glycerol to standard medium greatly increased the pigment content of the cells.

The effects of a large number of carbon compounds were tested by adding them to standard glucose medium. Pigment production was not increased by the addition of 1% of fructose, arabinose, xylose, sucrose, maltose, lactose, galactose, mannitol, arabitol, inositol, erythritol, quercitol, persietol or starch. The sodium and ammonium salts of formic, acetic, propionic, butyric, oxalic, lactic, citric, caproic, stearic and sebacic acids yielded negative results. A number of miscel-

laneous compounds such as acetone, methylglyoxal, ethyl propionate, acetaldehyde, aldol, allyl sulphate,  $\beta$ -ionone, phytol and a vitamin-A concentrate failed to stimulate pigmentation. On the other hand the alcohols, methyl, ethyl, *n*-propyl, *n*-butyl, *isobutyl*, *n*-amyl and particularly *isopropyl* favour pigment production. Ethyleneglycol, propyleneglycol, trimethyleneglycol, tetramethyleneglycol and *cyclohexane*-1:3-diol when added to the medium in 1% amounts produced very yellow cells (Table I).

Table I. *The effect of various carbon compounds on growth and pigmentation when added in 1% amounts to standard medium.*

Carbon compound	Cell weight g./100 ml.	10 day cultures $p_H$	Pigmentation Y/g.
Glucose	1.8	7.0	100
Methyl alcohol	1.2	7.0	186
Ethyl alcohol	1.6	7.0	149
<i>iso</i> Propyl alcohol	1.6	7.0	508
<i>n</i> -Butyl alcohol	1.7	7.0	231
<i>iso</i> Butyl alcohol	1.3	7.0	158
Amyl alcohol	1.0	7.0	296
Ethyleneglycol	1.5	7.0	720
Trimethyleneglycol	1.2	7.0	340
Tetramethyleneglycol	1.2	7.0	820
<i>cyclo</i> Hexanediol	1.2	7.0	344
Ethyl propionate	1.6	7.0	134
Ammonium acetate	0.7	8.4	14
Ammonium lactate	0.9	8.6	44
Acetone	0.9	7.0	124
Sodium glycerophosphate	1.6	7.1	205
Glycerol <i>plus</i> $Na_2HPO_4$	1.8	7.2	362
Glycerol	1.7	7.0	550

The similarities and differences which exist between the behaviour of *M. phlei* towards acetic acid and towards ethyleneglycol were found to be particularly interesting. Neither of these 2-carbon atom compounds is capable of supporting growth when supplied as the sole source of carbon but both are utilised in the presence of glucose. Stephenson and Whetham [1922] demonstrated that when acetates were added to a glucose medium there was an increase in the percentage of lipoids in the cells. However, as evidenced by the data in Table I and by additional experiments in which the hydrogen ion concentration was maintained around  $p_H$  7.0, no increase in pigments was observed when acetic acid was metabolised. In contrast to this is the marked increase in pigmentation observed in the presence of ethyleneglycol (Table II). The addition of this compound did not increase the yield of cells but as little as 0.2% definitely stimulated pigment production.

Table II. *The effect of ethyleneglycol on growth and pigmentation.*

Glucose g./100 ml.	Glycol g./100 ml.	Maximum cell weight g./100 ml.	Maximum pigmentation Y/100 ml.
1.0	0.0	0.41	50
1.0	1.0	0.41	250
5.0	0.0	1.65	326
5.0	0.2	1.42	896
5.0	1.0	1.45	1920
5.0	2.0	1.32	3240
5.0	5.0	1.09	3280

It is of course impossible to change one constituent of a medium without tending to modify a number of its properties. Thus when the source of carbon was

changed it was frequently found that the medium became very alkaline with the growth of the organisms. The explanation was apparent when sodium salts of organic acids had been used. Alkalinity was also noted when the concentration of glucose or glycerol had been reduced, as well as during the early stages of growth on glycerol. In both of these cases the source of alkalinity was largely attributable to ammonia liberated from asparagine. These data lend a new interpretation to the results of such workers as Weinzihr and Knapton [1927], who attached great significance to the fact that certain mycobacteria turned a 1% glucose medium alkaline whereas a 5% glycerol medium remained acid. Their results undoubtedly depended upon concentrations used rather than upon differences in the end-products formed from the two compounds. The early rise in the hydrogen ion concentration on the glycerol medium indicated to us that the asparagine was attacked preferentially. Total nitrogen determinations showed that during this period considerable quantities of nitrogen were lost to the atmosphere and that this loss might account for the lower yields observed on this medium. By inoculating a glycerol medium very heavily it was possible to accelerate the rate of growth so that nitrogen was rapidly tied up in the cells. Under these conditions it was observed that the yield was fully as great on glycerol as on glucose.

Many other factors besides the source of available carbon were found to affect the production of pigments by *M. phlei*. The first to be considered was the source of nitrogen. When the concentration of asparagine in the standard medium was lowered from 0.5 to 0.1 or 0.2%, growth and pigmentation were checked as they had been when glucose was the limiting factor. Therefore the increased pigment production observed with an excess of glucose could not have been due to a changed C : N ratio. When the concentration of asparagine was increased, the young growth was similar to that obtained under standard conditions but the pigment content reached a maximum at an earlier period and was then rapidly lowered as autolysis proceeded (Fig. 4). A similar autolysis involving rapid loss of pigments was produced by adding asparagine to 15-day standard glucose cultures. Ammonium salts, urea, peptone, caseinogen and a number of other compounds were substituted for asparagine, but the type of compound which served as a source of nitrogen had little effect on pigmentation, provided that care was taken to maintain the hydrogen ion concentration around neutrality.

The concentration of potassium in the medium is of considerable importance. In the first subculture from standard medium to an ammonium phosphate-glucose medium without potassium or other salt additions, growth was very slight but the pigment content per g. of cells was remarkably high (Table III). The addition of magnesium sulphate increased growth without affecting the colour of the cells but when potassium was added as the phosphate, pigment production was greatly depressed. The absence of potassium when glycerol was used instead of glucose had no effect upon the pigment content of the cells which was already very high. These results suggested: first, that the constituent of the medium which had prevented the accumulation of pigments on standard glucose might have been potassium, and second, that possibly glycerol or a similar compound was produced as an intermediate in the utilisation of glucose when potassium was not present.

The fact that pigmentation on glucose media was increased by lowering the concentration of potassium was confirmed in an experiment reported in Table IV. The data also show that lowering the concentration of phosphate favours pigment production on glycerol as well as on glucose as is suggested by the last row of figures in Table I. It will be seen from Table IV that lowering the concentra-

tion of phosphate, but not that of potassium, interfered with glucolysis, which in turn resulted in the liberation of ammonia from asparagine and the production of alkalinity. Determinations of the oxygen uptake on these media showed that lowering the concentration of phosphate limited the oxygen uptake but that within the range investigated the concentration of potassium had no effect.

The data in Table III indicate that increasing the concentration of iron decreased pigmentation. In Table V are given data which confirm this observation. Although ferric salts in moderate concentrations led to better growth, particularly on glycerol, concentrations of 0.1% ferric acetate definitely decreased the pigment content of the cells. Similar results were obtained with cupric salts.

The rôle of iron in the metabolism of *M. phlei* presents many problems. In Table VI are given data obtained by shaking washed cells in an acid solution of potassium iodide and titrating the liberated iodine with sodium thiosulphate. The oxidising agent, very possibly ferric ions, could be removed from the cell surface by washing with 95% alcohol. At the end of 4 days there was no trace of such an agent in any of the media. Those cultures which had contained the higher concentrations of ferric citrate were acid in reaction. It is not impossible that the lower pigment values observed in the presence of ferric and cupric salts, which were also adsorbed on the cells, were due to direct oxidation of the pigments.

A number of factors were studied which appeared to have no specific effect on pigmentation. These included ethylene gas<sup>1</sup> and salts of sodium, lithium, calcium, magnesium, selenium,<sup>1</sup> the oxidation-reduction potential, the light intensity and the temperature of incubation. The optimum reaction was found to be between  $p_H$  6.0 and 7.0. When the  $p_H$  was higher than 8.6 pigmentation was very poor in any medium.

As yet little has been done by way of correlating pigment content with the presence of other substances in the cell, but a correlation has been noted between the pigment content of the cells and catalase. Our studies have not been sufficiently exhaustive to establish this as an absolute parallelism but it is quite conceivable that an increase in catalase content might help to protect pigments from oxidation.

So far we have no direct evidence as to whether the pigment content of the cells increases because the pigments are required in certain physiological processes, or because certain agents stimulate synthetic processes, or because processes of destruction are inhibited. Until facts of this character are known, it is difficult to draw conclusions as to the function of the carotenoids in bacterial metabolism.

#### *Analysis of pigments.*

The pigments of *M. phlei* have already been studied by Chargaff [1930; 1933] who used the chromatographic technique. In 1930 he resolved the mixed pigments with calcium carbonate into three bands, one of which he identified as  $\beta$ -carotene. In 1933 he separated the pigments into carotenes, xanthophylls and

<sup>1</sup> Agents which brings about a chlorotic condition in higher plants.

xanthophyll esters, and put each fraction through columns of aluminium oxide. Four bands were revealed when the hydrocarbons were examined, but Chargaff concluded from spectrophotometric data that three of them were due to  $\beta$ -carotene. Evidently he did not realise that spectrophotometric data do not differentiate between  $\beta$ -carotene and kryptoxanthin, both of which we found upon repeating his work. From the xanthophyll esters he obtained a pigment similar to lutein and two bands which were not identified.

In our experience the best method of revealing the pigments of *M. phlei* was to put a light petroleum solution of the mixed pigments through a magnesium oxide column, and then to wash the column first with 20 % ether in light petroleum and then with chloroform. About a dozen bands could be revealed by this procedure.  $\alpha$ -Carotene,  $\beta$ -carotene, kryptoxanthin and esters of lutein, zeaxanthin and azafrin have been isolated and identified spectrophotometrically. The identity of the remaining pigments is being studied.

It was possible to separate the carotenes, their monohydroxy-derivatives and the esters of lutein and zeaxanthin and azafrin from the other pigments. 20 ml. of the original 95 % alcohol extract were pipetted into a small separating funnel to which 2.5 ml. of 5 % KOH were added. The mixture was extracted with light petroleum and the light petroleum fraction estimated quantitatively with a Lovibond tintometer. Chromatographic examination of this fraction (known as the PE-1 fraction) showed that it contained the carotenes, kryptoxanthin, a pigment which appeared to be the monohydroxy-derivative of  $\alpha$ -carotene and esters of lutein, zeaxanthin and azafrin. The other pigments remained in the alkaline alcohol. In Fig. 6 are given the quantitative data obtained for the PE-1

Fig. 6.

fractions from the cells used in Figs. 1 and 5. It will be seen that, although the values for the PE-1 fraction were high when total pigmentation was good, they were not high enough to account for more than half of the observed increase. Further, the PE-1 fraction reached a maximum at a much earlier point than did the remaining pigments. The percentage of pigments in the PE-1 fraction was estimated in all the experiments which have been reported in this paper, and in

general it was noted that whenever an agent such as glycol or potassium produced a change in total pigments, there was a change in the same direction in the carotenoid fraction. The highest percentages of pigments in the PE-1 fraction were obtained on glucose media where the absolute values were relatively low. It is difficult to interpret these results without a knowledge of the identity of the remaining pigments.

When glycerol or glycols were added to a glucose medium there was a tremendous increase in one pigment which has not yet been identified. In many respects the behaviour of this compound resembles that of phthiocol, the pigment isolated from *M. tuberculosis* by Anderson and Newman [1933]. It was yellow and ether-soluble in acid solution, but turned deep red and became water-soluble in alkaline solutions. In the chromatographic column it appeared above xanthophyll as a deep red line which turned purple when the column was washed with chloroform. In the presence of traces of water a blue colour was developed. When ferric salts were added to the medium the amount of this pigment was decreased. Quantitative estimates were made by measuring the red Lovibond units in the alkaline alcohol solution from which the PE-1 fraction had been extracted. It was found that the absolute amount of this pigment increased long after cell autolysis had been initiated, suggesting that it was an end-product in metabolism.

#### SUMMARY.

The effects of a number of factors on the gross pigmentation of *M. phlei* have been studied. On a synthetic glucose-asparagine medium the pigment content of the cells was relatively low. As growth proceeded the cells became increasingly yellow and this was found not to be due to their age or to the influence of the heavy pellicle. A similar increase in pigmentation was induced by lowering the concentration of potassium or phosphate ions in the medium. Increasing the concentration of ferric salt tended to prevent pigment formation. When glycerol was substituted for glucose pigmentation was greatly increased. The concentration of potassium was without effect on pigmentation in the presence of glycerol, but phosphates and ferric or cupric salts decreased the colour of the cells. The addition of alcohols or glycols but not of sugars, sugar alcohols, acids or many other carbon compounds to the standard medium increased pigment production. An excess of asparagine in the medium led to rapid cell autolysis and destruction of the carotenoids. The substitution of ammonium salts, urea, peptones and other sources of nitrogen for asparagine had no effect upon pigmentation when the reaction of the medium was controlled. However, if the  $p_H$  was allowed to rise above 8.6, the cells were never highly coloured. Ethylene and the salts of sodium, lithium, calcium, magnesium and selenium, the oxidation-reduction potential, the light intensity and the temperature of incubation were without specific effect upon pigmentation.

In the absence of suitable sources of energy *M. phlei* attacked asparagine with the liberation of ammonia and the production of alkalinity. This was observed when the concentration of glucose or of phosphate limited glucolysis, or in the early stages of growth on glycerol. The absence of potassium checked growth but not the oxygen uptake of the cells or glucolysis. Cells grown in the presence of ferric or cupric salts were capable of oxidising potassium iodide to iodine.

At least a dozen different pigment bands were observed when the pigments were resolved on a magnesium oxide column. Of these  $\alpha$ -carotene,  $\beta$ -carotene and kryptoxanthin were identified and the presence of esters of lutein, zeaxanthin and azafrin was established. A method was devised for separating this group of

known pigments and determining them quantitatively. They were found to vary directly with gross pigmentation but no close parallelism was noted and their increase in the presence of glycerol *etc.* was never enough to account for the total increase in pigments. A pigment somewhat resembling phthiocol was largely responsible for the increased pigmentation observed in the presence of glycerol and the glycols. This pigment, as contrasted with the carotenoids which generally reached a maximum before the cells began to autolyse, appeared to be an end-product since it increased in absolute amount until the cells were almost completely autolysed.

## CCCV. THE PURIFICATION OF CHOLINE-ESTERASE.

By EDGAR STEDMAN AND ELLEN STEDMAN.

*From the Department of Medical Chemistry, University of Edinburgh.*

*(Received September 12th, 1935.)*

ALTHOUGH it was previously known from pharmacological experiments, quoted in our earlier papers, that certain body fluids brought about the enzymic decomposition of small amounts of acetylcholine, the first demonstration of the existence of a specific enzyme which catalyses the hydrolysis of this ester, as well as of other esters of choline, was that of Stedman *et al.* [1932] who termed the enzyme in question choline-esterase. This demonstration depended primarily upon the discovery that whereas purified preparations of certain known ester-hydrolysing enzymes, such as liver esterase and pancreatic lipase, were unable to accelerate the hydrolysis of esters of choline to an extent detectable by chemical means, blood serum from the horse readily effected such an acceleration, a result which was so definite and of such a convincing nature that further work on the subject could hardly be other than of a corroborative kind. This has, in fact, proved to be the case, ample corroboration of the original conclusions of Stedman *et al.* [1932] being offered by the work of Stedman *et al.* [1933] and of Ammon [1934]. Nevertheless there remained some doubt as to the degree of specificity of choline-esterase, for blood serum from the horse, which was usually employed as source of the enzyme in question, exhibited a pronounced enzymic activity towards other types of esters, in particular towards methyl butyrate, and it was therefore uncertain whether part of this activity might not be due to choline-esterase. Stedman *et al.* [1932], in their original work on this subject, had examined this problem to some extent. They succeeded in effecting a considerable purification of the enzyme and were able to show that, as purification proceeded, the activity of the preparation towards methyl butyrate diminished considerably relatively to its activity towards esters of choline. But they did not succeed in obtaining preparations which were completely devoid of activity towards simple esters, thus leaving open the possibility that choline-esterase might exhibit a small activity towards such esters. Further evidence on this point, depending upon a much more extensive purification of the enzyme, has now been obtained and is described in the present communication.

### *Preliminary purification of choline-esterase.*

In the work here described blood serum from the horse has formed the source of choline-esterase, and it has been found necessary to submit this to a preliminary purification by fractional precipitation with ammonium sulphate. The experimental basis of this method of purification has already been described by Stedman *et al.* [1932]. In the course of the last three years, however, much experience has been gained in working up large volumes of serum and this has enabled us to define with much greater precision than before the conditions necessary for the successful application of the method. By using the Sharples "supercentrifuge", which, in fact, appears to be practically indispensable for the process, large volumes of serum can be readily and successfully worked up.

The procedure finally adopted is as follows. 250 g. of ammonium sulphate are dissolved in 1 litre of horse serum. The precipitate is removed and rejected, whilst the centrifugate is treated with further ammonium sulphate at the rate of 15 g. per 100 ml. When this has dissolved, 0.5 *N* acetic acid is added slowly and with stirring, 78 ml. being employed for the centrifugate from 1 litre of serum. The mixture is now allowed to stand for  $2\frac{1}{2}$ – $2\frac{3}{4}$  hours, after which the precipitate, which contains the bulk of the enzyme, is centrifuged off and the enzyme eluted from it with 300–400 ml. of a solution containing 350 g. of ammonium sulphate in 1 litre of water. The eluate is now separated and kept for a few hours or, if convenient, overnight. During this time a precipitate usually forms, in which case it is removed and rejected. The centrifugate from this last process is measured and treated with solid ammonium sulphate (5 g. per 100 ml.) and sufficient 0.5 *N* acetic acid (about 5 ml.) to render it faintly acid to litmus. The enzyme separates with the precipitate. After about 30 min. the material is centrifuged, the solid dissolved in the smallest possible volume of water and the solution so obtained dialysed in collodion membranes against water saturated with chloroform until free from ammonium sulphate. The product, after removal of some protein which separates during dialysis, consists of about 50 ml. of a clear solution which varies, in different batches, from light to dark brown in colour according to the amount of haemoglobin contained in the serum from which it was prepared. Its choline-esterase activity is from 4 to 6 times that of the original serum, so that the yield of enzyme is approximately 20%. The activity of the preparation can be conveniently and accurately determined by the titration method of Stedman *et al.* [1933] using bromothymol blue as indicator and, preferably, butyrylcholine as substrate, since, of the choline esters so far examined, this ester is hydrolysed the most rapidly by choline-esterase. Having determined the activity of the preparation, the degree of purification effected can be readily ascertained by evaporating 1 ml. to dryness on a water-bath, weighing the solid residue and hence calculating the "weight number" of the preparation. For the purposes of the present work we define the weight number of a preparation as the number of ml. of 0.02 *N* sodium hydroxide required to neutralise the butyric acid liberated at 30° from butyrylcholine in 20 min. at  $p_H$  7.4 by the choline-esterase associated with 1 g. of the solid material contained in the preparation, the actual titration being carried out under the conditions described in our earlier publications. For example, in an actual preparation the butyric acid liberated in 20 min. by 0.25 ml. of the final solution required 9.8 ml. of 0.02 *N* alkali for neutralisation, whilst 1 ml. of the solution yielded on evaporation 0.078 g. of solid residue. The weight number of the preparation was thus  $9.8 \times 4/0.078 = 503$ . The corresponding figure for the original serum cannot be determined accurately at  $p_H$  7.4, but if a value of 100, which is a maximum figure, be assumed it is evident that the process has resulted in at least a 5-fold purification of the enzyme. This degree of purification is an average one. Occasionally it is somewhat smaller; at times much greater. Thus, final products have been obtained with weight numbers ranging from about 300 to 1500. Preparations of this type retain their activity for months if stored in a refrigerator but deteriorate moderately rapidly if kept at room temperature.

Certain details of the above process are susceptible of considerable modification without significantly influencing the final result. Thus, it appears to be immaterial whether the first precipitation is made with 250 or 200 g. of ammonium sulphate per litre of serum, provided, in the latter case, that the second precipitation is made with 20 g. of ammonium sulphate per 100 ml. of centrifugate. On the other hand, much care must be exercised with respect to the acidification at

the second stage. It is, in fact, upon this process that the success of the operation mainly depends. The use of too high a concentration of acid leads to a diminution both in the yield and the purity of the product, whilst with too low a concentration the degree of purification is small. The time factor is of equal, if not greater, importance. If the acidified material is worked up after too short an interval of time, little purification is achieved; with too great an interval, the yield is curtailed and the purity diminished. We interpret these results as indicating that the function of the acetic acid is to denature part of the protein and so render it insoluble in the ammonium sulphate solution used for the elution of the enzyme. Such denaturation must be as extensive as possible, provided it is not pushed beyond the limits at which sufficient soluble protein remains to act as a carrier for the enzyme.

*Purification of choline-esterase by adsorption.*

Attempts to adsorb the enzyme directly from serum completely failed, as is illustrated by the following experiment. About 30 ml. of serum were shaken with fuller's earth and centrifuged. The centrifugate (27 ml.) was made distinctly acid to litmus by the addition of 1.2 ml. of 0.5 *N* acetic acid, shaken with 1 g. of kaolin and again centrifuged. The new centrifugate (23 ml.) was then treated with 4 ml. of a suspension of aluminium hydroxide and the latter removed. At each stage a determination was made of the weight number of the centrifugate, the titration being made at  $p_H$  8.0, with the following results: serum, 61.5; after fuller's earth, 73.1; after kaolin, 81.5; after alumina, 85.2. The corresponding titration figures were 6.5, 7.35, 7.1 and 6.05 ml. respectively. In no case was any enzyme removed by the adsorbent, the diminution in the titration figure for the last centrifugate being accounted for by the dilution caused by the addition of the suspension of alumina. A small but steady increase in purity occurred, however, at each stage. That produced by the fuller's earth was evidently partly due to the removal of inactive material and partly to the removal of an inhibitor, whilst that caused by the kaolin and alumina was due solely to the former process. The effect of fuller's earth in increasing the activity of serum has also occasionally been observed with preparations made by the process described in the preceding section, but the effect is not a constant one with such preparations.

In view of the foregoing results subsequent adsorption experiments have been made with purified preparations of the enzyme. These have resulted in the demonstration that choline-esterase can be removed from such solutions by alumina provided they have first been rendered distinctly acid to litmus by the addition of acetic acid. Kaolin, however, is ineffective either in alkaline or acid solution. Removal of the enzyme from the alumina adsorbate can be effected either by treatment with 0.025 *N* ammonia or with phosphate buffer of  $p_H$  8.0. The former eluent sometimes fails, particularly when adsorption has been made from a preparation which has already been purified by adsorption, but the phosphate buffer is always effective if used in sufficient quantity and high enough concentration. One disadvantage of the latter eluent is that the activity of the eluate cannot be measured until the phosphate has been removed by dialysis, for, in the concentration which it is necessary to employ, it exerts a pronounced inhibitory action on choline-esterase. Purification by these means is illustrated by the following example.

50 ml. of a preparation of choline-esterase of weight number 450 were made acid by the addition of 6 drops (0.3 ml.) of 0.5 *N* acetic acid, 6 ml. of a suspension of aluminium hydroxide were then added slowly, with continuous shaking, and the mixture was centrifuged. Previous experience enabled us to judge from

the colour of the centrifugate that adsorption of the enzyme was incomplete. It was therefore similarly treated with 5 ml. of a suspension of ferric hydroxide and again centrifuged. Adsorption was still obviously incomplete. The centrifugate was therefore mixed with a further 5 ml. of alumina, after which 0.25 ml. of the centrifugate gave a titration figure of 1.5 ml. as compared with 8.2 ml. for the original preparation. A final adsorption with 10 ml. of the alumina suspension was therefore carried out. The centrifugate, which now measured 75 ml., still contained some enzyme as shown by the titration figure, using 0.25 ml. of the centrifugate, of 0.85 ml. in 20 min.; this represented about 15% of the enzyme present in the original preparation.

The various alumina adsorbates were united and washed with an equal volume of water. They were then stirred with 20 ml. of 0.025 *N* ammonia, allowed to stand for 1 hour, and centrifuged. The ferric hydroxide adsorbate was similarly eluted with 5 ml. of the ammonia solution. Both eluates were active and of similar degrees of purity, as shown by the following quantitative data: alumina eluate, weight number 1833, titration figure for 0.25 ml. 5.5 ml.; ferric hydroxide eluate, weight number 1766, titration figure 3.0 ml. From this one experiment ferric hydroxide appears to be as efficient an adsorbent for choline-esterase as is aluminium hydroxide, but it nevertheless offers no advantage over the latter and has therefore not been used in further work.

The eluate from the alumina adsorbate was acidified and the enzyme again adsorbed on alumina, 8 ml. of the suspension being required. Elution from the washed adsorbate was effected with 10 ml. of *M*/3 phosphate buffer of  $p_H$  8.0. After dialysis, the preparation had a weight number of 3098, 0.25 ml. giving a titration of 6.35 ml. A final adsorption was now made with 4 ml. of alumina, this effecting the complete removal of the enzyme from the last eluate. In this instance the adsorbate was washed with a few ml. of 0.025 *N* ammonia and then eluted with 10 ml. of phosphate buffer. The ammonia washings were, however, found to be active, 0.25 ml. giving a titration figure of 5.75 ml. whilst the weight number proved to be 4423. The dialysed phosphate eluate had a weight number of 3083 (titration: 0.5 ml. required 3.7 ml. alkali) and thus showed no improvement as regards purity over the solution from which it was prepared.

The foregoing example is not the most successful purification by adsorption which we have carried out, but it has been quoted because it best illustrates the various processes involved. Whilst it must be emphasised that, in applying the adsorption method to choline-esterase, the efficiency of the method must be checked at each stage, it might here be pointed out that the best results are usually obtained by adsorbing the enzyme on alumina, eluting it with ammonia, and repeating these processes until the latter eluent is ineffective. Elution can then be made with phosphate. In one instance this procedure was exceedingly effective, the ammonia eluate from the first adsorption having a weight number of 2267 as compared with 675 for the original preparation. A second adsorption gave an adsorbate from which the enzyme could no longer be eluted with ammonia, but, using phosphate, a product was readily obtained with a weight number of 5647.

#### *Specificity of choline-esterase.*

Many specimens of choline-esterase purified by adsorption have been examined for possible activity towards methyl butyrate, but in no case has such activity been detected. Thus, using 0.25 ml. of a preparation of weight number 3098 with 0.25 ml. of methyl butyrate dissolved in 100 ml. of water at 30° as substrate, 0.25 ml. of 0.02 *N* alkali was required to maintain the  $p_H$  of the solu-

tion at 7.4 for 20 min.; the same volume of alkali was required in a blank experiment without enzyme. On the other hand, with butyrylcholine as substrate under the usual conditions 6.35 ml. of alkali were required. Similar results were obtained with the preparation, mentioned above, of weight number 5647. It must be concluded that choline-esterase has no significant action on methyl butyrate.

#### SUMMARY.

Choline-esterase cannot be adsorbed directly from blood serum from the horse by adsorbents such as aluminium hydroxide, but by submitting the enzyme to a preliminary purification by a process which consists essentially of fractional precipitation with ammonium sulphate combined with partial denaturation of the serum proteins by means of acetic acid, preparations can be obtained which are susceptible of further purification by adsorption. Among the adsorbents examined, aluminium and ferric hydroxides were found to take up the enzyme from acid, but not from neutral or faintly alkaline, solutions. Kaolin is totally ineffective. Elution from the adsorbates can usually be made with 0.025 *N* ammonia. As purification proceeds, however, this eluent ceases to be effective. Elution can then be carried out with *M*/3 phosphate buffer of  $p_H$  8.0.

Preparations of choline-esterase the purity of which is from 50 to 100 times that of serum have been made by the above methods. Such preparations have no detectable activity towards methyl butyrate.

The expenses of this investigation have been partly met by grants from the Earl of Moray Research Fund of Edinburgh University.

# CCCVI. THE DISTRIBUTION OF GLYCOGEN IN THE REGIONS OF THE AMPHIBIAN GASTRULA; WITH A METHOD FOR THE MICRO-DETERMINATION OF GLYCOGEN.

By NORMAN GEORGE HEATLEY.

*From the Biochemical Laboratory, Cambridge.*

*(Received September 27th, 1935.)*

LINDERSTRØM-LANG AND HOLTER [1931] have described a micro-technique of great beauty, which they have used, amongst other things, for the estimation of reducing sugars [1933]. With the help of this technique, the Pflüger [1904] method for the quantitative precipitation of glycogen was adapted to the estimation of small amounts of this substance. A number of difficulties were met with, and the experimental procedure is given below in some detail, as it was found that slight alterations in the method might cause considerable errors.

Until a short time ago it was maintained by histologists [*e.g.* Woerdemann, 1933] that whereas the neural plate of the amphibian gastrula was rich in glycogen, the mesoderm, which is formed by invagination of the neural plate ectoderm, contained almost none. It has been suggested by Pasteels [1935], however, that the mesoderm does in fact contain glycogen, but that it is washed out of the cells during the fixing process. This suggestion is supported by Pasteels by experimental evidence which is shortly to be published.

When the method for the micro-estimation of glycogen had been satisfactorily worked out, direct chemical measurements were made of the glycogen contents of various regions of the gastrula, which were isolated by dissection.

## I. *Micro-estimation of glycogen.*

*Principle.* The tissue is weighed out into glass tubes measuring  $5 \times 120$  mm. and digested by heating with potassium hydroxide. The glycogen is then precipitated by adding alcohol, and flocculated by heating to boiling-point [Good *et al.*, 1933]. It is then centrifuged down and washed twice with absolute alcohol, after which it is hydrolysed with acid, which is subsequently neutralised; the reducing sugar formed is then estimated by the method of Linderstrøm-Lang and Holter [1933].

*Experimental procedure.* 1. About  $35\mu\text{l.}$  of 30% potassium hydroxide are measured into the small tube, which is stored in a  $\text{CO}_2$ -free atmosphere till the tissue has been weighed out.

2. The tissue is added and the tube is capped.

3. The tube is heated in a steam-bath for 20 min.

4. With the same pipette which has been used for measuring out the potash,  $35\mu\text{l.}$  of water and then  $105\mu\text{l.}$  of absolute alcohol are added. (Unless the alkaline solution is diluted before adding the alcohol, two layers are formed which will not mix.)

5. The contents of the tube are thoroughly mixed by rotating and at the same time stirring with a fine platinum wire.

6. The tube is immersed in the steam-bath for a few seconds to flocculate the glycogen, care being taken that it is removed before the contents spurt out.

7. The tube is centrifuged at 3500 r.p.m. for 15 min.

8. The clear centrifugate is removed and discarded by inverting the tube and drawing it off by means of a fine pipette.

9. The residue is washed by discharging about 100  $\mu$ l. of absolute alcohol from a fine pipette on to the solid at the bottom of the tube.

10. The tube is centrifuged at 3500 r.p.m. for 5 min., and the centrifugate is removed as before.

11. The washing process is repeated once more.

12. After the final washing, the centrifugate is discarded, and the last traces of alcohol are removed from the residue by placing the tube in the steam-bath for a few minutes.

13. About 35  $\mu$ l. of 0.6 *N* hydrochloric acid are then added in such a way that the deposit adhering to the upper parts of the tube is washed down. (This operation requires considerable care if it is to be effective, on account of the small volume of fluid used.)

14. A small cube of paraffin wax, weighing 20–30 mg., is added, and the tube is placed in the steam-bath for 2½ hours.

15. After the hydrolysis, the tube is removed and whilst still hot is inverted and rotated so that an even coating of wax is spread over the upper parts of the tube.

16. A stirrer, consisting of a small glass sphere filled with iron filings, is added, and the thin film of wax on the actual surface of the hydrolysate is broken by rotating the tube whilst it is held against an electromagnet.

17. A micro-drop of 0.05 % aqueous thymol blue is added and the contents are titrated against *N* NaOH till a bluish grey colour is obtained. *N* NaOH is used in order to keep the volume as small as possible, and the end-point is often overshot; this is easily adjusted, however, by adding dilute (0.1 *N*) hydrochloric acid from a finely drawn out capillary. When the tubes have been neutralised they are kept in a CO<sub>2</sub>-free atmosphere.

Blanks are set up by taking 35  $\mu$ l. of 0.6 *N* HCl, adding a drop of thymol blue, neutralising and adding 50  $\mu$ l. of buffer before adding the iodine; the films of sulphuric acid and starch are formed as usual. (For details of the sugar estimation reference must be made to Linderstrøm-Lang and Holter [1933].)

*Accuracy of the method.* This was tested by a number of experiments, of which the following are typical.

15  $\mu$ l. of approximately 1.0 % glycogen solution were accurately measured into the bottom of each of six tubes. The glycogen in three of them was hydrolysed directly, whereas the remaining tubes were heated for 20 min. with 30% potash, and the glycogen was precipitated in the manner described above before being hydrolysed. The sugar was then estimated in all tubes, the following thiosulphate titrations being obtained:

Hydrolysed at once		Hydrolysed after precipitation	
Titration	Vol. of thiosulphate $\equiv$ reducing sugar	Titration	Vol. of thiosulphate $\equiv$ reducing sugar
12.90	29.50	13.25	29.15
12.80	29.60	13.30	29.10
12.90	29.50	13.25	29.15

Mean blank value 42.40.

Thus there is a small loss of glycogen during the precipitation. It remained to determine in what way this loss is related to the total amount of glycogen present.

This was done by taking samples of equal volumes of different glycogen solutions of known relative concentration and estimating the glycogen in them by this method. The following results are typical:

Sample	Conc. of glycogen %	Titration	Vol. of thiosulphate $\equiv$ reducing sugar
1	1.00	11.70	29.90
2	1.00	11.35	30.25
3	0.20	35.40	6.20
4	0.20	35.35	6.25
5	0.10	38.20	3.40
6	0.10	38.50	3.10
7	0.05	39.75	1.85
8	0.05	39.85	1.75

Mean blank value 41.60.

These results have been plotted in Fig. 1.

It will be seen that the points lie on a straight line which does not quite pass through the origin. The fact that the points lie on a straight line shows that the amount of glycogen lost during the precipitation is a constant percentage of the

Fig. 1.

total amount present; the fact that the line does not pass through the zero of abscissae suggests that the blank value is too high, but only by about  $0.4\mu\text{l}$ . A correction is, of course, made for this.

The maximum error which has been observed in a series of parallel estimations is  $\pm 0.3\mu\text{l}$ . of  $0.05N$  thiosulphate. Now  $2.0\mu\text{l}$ . of  $0.05N$  thiosulphate are equivalent to approximately  $0.01$  mg. of glycogen. Therefore there should be a maximum error of less than  $\pm 2\gamma$  of glycogen.

The loss of about  $1.5\%$  incurred during the precipitation does not affect the results, since it has been found most convenient to standardise the reagents by means of a control estimation of a solution of glycogen of known strength.

Whether the same degree of accuracy may be expected when working with tissues instead of with solutions of pure glycogen is a point which cannot be tested, since no glycogen-containing tissues are available which are sufficiently homogeneous for this purpose.

## II. Distribution of glycogen in the regions of the amphibian gastrula.

A preliminary experiment was performed with the gastrula of the axolotl, but the remaining work was done on *Triton alpestris*. Each gastrula was divided into the following regions:

1. Neural plate ectoderm.
2. Ventral ectoderm.
3. Mesoderm.
4. Endoderm.

The embryos were all in the "late gastrula" stage, though some were definitely more advanced than others.

*Treatment of tissue.* With such small quantities as were used, it was quite out of the question to determine the wet weight of the tissue. On the other hand, care had to be taken that during the drying of the tissue (preparatory to obtaining its dry weight) no glycogen was broken down. The material equivalent to two or three embryos was used for each determination, and as each piece was dissected out it was dropped into absolute alcohol, a procedure calculated to stop effectively all enzyme action. When enough had been collected, the material was placed in a punt-shaped vessel of platinum and dried for 2 hours at 100° in a gentle stream of dry air. When cool, the punt was weighed on a micro-balance; some of the material was then removed, after which the punt was reweighed. The dried tissue was more or less compact, and did not adhere at all to the vessel in which it had been dried. The most satisfactory way of transferring the tissue to the glass tube is to touch it with a needle which has been dipped in vaseline and wiped almost clean, and then to detach it from the needle into the tube with a gentle tap.

The assumption has been made that from the time of excision of the tissue none of its glycogen has been lost. The absolute alcohol would fix the material practically instantaneously, and as it would have access to both sides of the tissue it is unlikely that there would be any appreciable loss of glycogen.

A more serious source of error lies in the fact that a certain amount of material will be dissolved from the tissues by the absolute alcohol, and thus give a low value for the dry weight of the material. It is probable that there will be more loss from the tissues of some regions than from others, due to the greater amount of alcohol-soluble substances. The exact loss could easily have been determined if sufficient material had been available.

Table I.

	Neural plate ectoderm		Ventral ectoderm		Mesoderm		Endoderm	
	Wt. of tissue mg.	Glycogen %	Wt. of tissue mg.	Glycogen %	Wt. of tissue mg.	Glycogen %	Wt. of tissue mg.	Glycogen %
Axolotl	1.13	17.1	—	—	1.16	11.1	—	—
	1.34	15.0	—	—	1.11	11.0	—	—
	1.25	15.0	—	—	—	—	—	—
<i>Triton alpestris</i> 1	0.43	19.7	—	—	0.54	12.4	0.93	8.8
	2	—	—	—	0.32	16.1	1.00	8.0
	3	0.40	18.6	0.75	15.8	0.36	10.1	1.80
		0.30	19.1	0.65	16.9	0.48	8.8	—
	4	0.76	17.5	0.59	15.1	0.67	10.9	1.15
		—	—	—	0.64	9.3	—	—
	5	0.33	23.6	0.79	16.5	—	1.34	7.2
	6	—	—	0.78	14.7	0.36	13.2	1.33
		—	—	—	—	—	—	5.9

*Results.* These are given in Table I. There is a considerable scatter, due, partly, no doubt, to biological variation, but mainly to the extremely unfortunate fact that the indicator used for neutralisation after hydrolysis contained a small amount of alcohol, which reacted to some extent with the iodine to form iodoform. As the reagents were standardised against a glycogen solution of known strength, the error would be small, except in cases where the amount of tissue taken was smaller than usual: here a high value would be found. Subsequent experiments with this particular indicator showed that the error could not be greater than 10 %, though it was too erratic for a correction to be applied. It is emphasised, therefore, that the results as they stand are slightly too high.

#### DISCUSSION.

The results described above lend direct support to the view that the mesoderm of the amphibian gastrula contains a certain amount of glycogen. It is clear, on the other hand, that during invagination through the dorsal lip of the blastopore there is a distinct loss of glycogen, since the mesodermal roof of the archenteron contains less than the uninvaginated dorsal ectoderm (presumptive neural plate). The significance of this for our knowledge of the metabolism of the organisation centre and the liberation of the evocator may be considerable. A discussion of this aspect of the problem will be found in the paper of Waddington *et al.* [1935].

#### SUMMARY.

1. A method is described for the estimation of glycogen in amounts of tissue of the order of 1 mg.; the probable error is less than  $\pm 2\gamma$  of glycogen.
2. The amounts of glycogen in the various morphologically distinct regions of the amphibian embryo during gastrulation have been estimated. The dorsal ectoderm has most, the yolk endoderm least and the ventral ectoderm occupies an intermediate position. During invagination, and hence during the liberation of the evocator, there is a diminution of about 35 % of the glycogen in the invaginating cell layers.

The author is much indebted to Mr C. H. Waddington and to Fr. J. Kriebel, who performed the isolations of the embryonic regions. This work was carried out during the tenure of a grant from the Department of Scientific and Industrial Research.

# CCCVII. THE CARBAMIDO-ACID AND HYDANTOIN OF ARGININE.

BY WILLIAM ROBERT BOON AND WILLIAM ROBSON.

*From the Department of Physiology, University of London  
King's College.*

(Received October 1st, 1935.)

LIPPICH [1906; 1914] AND DAKIN [1918] demonstrated the usefulness of the carbamido-acids and hydantoins for the identification of the corresponding  $\alpha$ -amino-acids and Dakin [1918; 1920] elaborated methods for the isolation of proline and hydroxyproline, in the form of their hydantoins, from mixtures of amino-acids. More recently Boyd [1933] showed that the carbamido-compounds could be utilised for isolating in excellent yield certain  $\alpha$ -amino-acids from protein hydrolysates.

Reference to the literature, however, shows that whilst our knowledge of the carbamido-acids and hydantoins derived from the mono- and di-carboxylic  $\alpha$ -amino-acids is fairly complete, that regarding the corresponding derivatives of the basic  $\alpha$ -amino-acids is very limited. Apart from 5- $\delta$ -carbamidobutylhydantoin and 5- $\delta$ -aminobutylhydantoin, recently shown by Hoppe-Seyler [1933] to be derivatives of lysine, and citrulline, claimed by Wada [1930] to be  $\alpha$ -amino- $\delta$ -carbamidovaleric acid, only the phenylcarbamido- and phenylhydantoin derivatives of ornithine [Herzoy, 1902; Sørensen, 1903; 1905] and of lysine [Herzoy, 1902] are known.

It appeared to us of interest therefore to attempt the preparation of the carbamido-acid and hydantoin derived from arginine, a quantity of which we possessed in the form of its monohydrochloride.

When an aqueous solution of arginine monohydrochloride was heated with potassium cyanate on the water-bath for about an hour and then allowed to cool, a heavy crystalline mass gradually separated. The mother-liquor was alkaline to litmus and our first impression was that this was due to the hydrolysis of the excess of cyanate employed. The crystals which had separated were collected, washed several times with small quantities of distilled water and finally recrystallised from hot water.

A cold saturated aqueous solution of the new compound, which possesses in a marked degree the property of forming supersaturated solutions, was definitely alkaline to litmus, its  $p_H$  being in the region of 11. Moreover, it did not appear to be more soluble in cold aqueous sodium hydroxide than in cold water, nor was carbon dioxide evolved when its hot aqueous solution was treated with sodium carbonate. The apparent inactivity of the carboxyl group of the original arginine molecule has led us to regard the formula of the new carbamido compound as

Of the two formulae, the former is more probably the correct one in view of the fact that the compound is stable in hot aqueous solution whilst triacetylarginine, shown by Bergmann and Koster [1926] to have a piperidone nucleus, is decomposed, even by cold water, into acetylurea and acetylmornithine.

The carbamido-compound is naturally very soluble in dilute mineral acids. On evaporating a solution of the compound in hydrochloric acid on the steam-bath to small bulk, there separated on standing for several days large prismatic crystals consisting of arginine hydantoin hydrochloride. Recrystallisation of the hydantoin may be effected either by dissolving it in a small bulk of hot concentrated hydrochloric acid and allowing the solution to cool, or by addition of alcohol to a highly concentrated aqueous solution. Analyses of the product so obtained indicate that it contains one molecule of water of crystallisation, which it loses slowly on heating at 60°.

Picturing the structure of the hydantoin thus derived from arginine as

it may be regarded as the mother substance of  $\alpha$ - $\delta$ -bisguanidino-*n*-valeric acid anhydride

synthesised by Zervas and Bergmann [1928] and shown by them to agree in every respect with the so-called arginylarginine originally obtained by Fischer and Suzuki [1905] by treating arginine methyl ester with a concentrated solution of hydrogen chloride in methyl alcohol.

#### EXPERIMENTAL.

*Carbamido-arginine.* Arginine monohydrochloride (10 g.=1 mol.), prepared from gelatin by the method of Cox [1928] was dissolved in water (80 ml.) and to the solution was added solid potassium cyanate (10 g.=1.25 mol.) with shaking. The mixture was heated on a water-bath for 1 hour and was then set aside to cool overnight. Next morning a heavy crystalline precipitate of the carbamido-acid had separated. The crystals were collected at the pump and recrystallised from the minimum amount of boiling water. The product weighed 8.7 g. (84% of theory) and melted at 172°. Dried at 110° *in vacuo*, it gave on analysis N, 32.0%.  $\text{C}_7\text{H}_{16}\text{O}_8\text{N}_6$  requires N, 32.2%.

*Arginine hydantoin.* 5 g. of carbamido-arginine as prepared above were dissolved in 20 ml. of hydrochloric acid (2*N*) and the solution placed on the boiling water-bath and evaporated to a thick syrup. The syrup was set aside and after some 6 days large flat prisms gradually separated. These were collected and recrystallised by dissolving them either in (i) a few ml. of hydrochloric acid and evaporating the solution almost to dryness, after which crystallisation slowly occurred on standing, or (ii) a few ml. of water and evaporating the solution almost

to dryness; on the addition of a large excess of alcohol, the hydrochloride separated as an aggregate of tiny prisms. The yield was almost quantitative. The product melted sharply at 100°. When dried at 60° for a week, it gave on analysis N, 29.2; Cl, 15.2%.  $C_7H_{14}O_2N_5Cl$  requires N, 29.7; Cl, 15.1%.

# CCCVIII. OSMOTIC EQUILIBRIA OF HAEMOCYANIN IN A GRAVITATIONAL FIELD.

By JEAN ROCHE, ANDRÉE ROCHE, GILBERT SMITHSON ADAIR  
AND MURIEL ELAINE ADAIR.

*From the Biochemical Laboratory, University of Marseilles and the Physiological Laboratory, Cambridge.*

*(Received September 9th, 1935.)*

RECENT work on the sedimentation of haemocyanin in the ultracentrifuge has been reviewed by Svedberg [1933], who has given the value 5,100,000 for the molecular weight of the haemocyanin of the snail. A brief note on the possibility of demonstrating the existence of very large molecules by osmotic methods has been published by Adair *et al.* [1934].

The present communication records a method for the preparation of the haemocyanins, which eliminates certain impurities, and data of the osmotic pressures of blood (or haemolymph), once crystallised and thrice crystallised haemocyanins, using material obtained from the snail (*Helix pomatia*), the crab (*Carcinus moenas*) and the octopus (*Octopus vulgaris*). In addition, a method is described for studying the distribution of proteins in a gravitational field. This method differs from those used by previous workers for large colloidal particles in a gravitational field or for the proteins in centrifugal fields, in that two phases are equilibrated in a gravitational field by means of a semipermeable membrane. The thermodynamical treatment of such equilibria has been given by Adair [1935].

## 1. Preparation of haemocyanin.

The comparison of a number of preparations of haemocyanin is of interest, for it is possible that the average size of the particle might depend on the procedure adopted for separating the protein from impurities. In this work, the following preparations have been examined.

(a) Blood, dialysed against a mixture of salts calculated from the analyses of snail's blood [Arvanitaki and Cardot, 1932], or against the *M/15* phosphate mixtures used for the preparations 2 and 3.

(b) Once crystallised haemocyanin. The haemocyanins of the snail, the crab and the octopus have been prepared by prolonged dialysis of the bloods at 0° against distilled water. It has been known since the publication of Dhéré's researches [Dhéré, 1908; Dhéré and Burdel, 1914] that on dialysis of the blood of *Helix pomatia*, crystalline haemocyanin is deposited after a period varying from a few weeks to two months. Although the haemocyanins are globulins, precipitating at the isoelectric point, many authors have stated that with the blood of certain animals, including *Limulus*, no precipitation or crystallisation is obtained on dialysis. In this work it has been observed that even with animals such as *Limulus*, the protein is deposited in an amorphous or a crystalline state, according to the rapidity with which diffusible ions are eliminated, although in certain cases it may be necessary to continue dialysis for at least two months.

The vessels used for dialysis were made of sparingly soluble glass. In some experiments, the time required for the formation of a precipitate was reduced by

the addition of a trace of potassium hydrogen phosphate or of an isoelectric acetate buffer solution to the water used for dialysis.

Each preparation of octopus haemocyanin was made from the blood obtained by the vascular puncture of about 5 animals. In the cases of *Helix* and *Carcinus* several hundred animals were required. The blood of *Helix* was obtained by cardiac puncture; it may be noted that the majority of the preparations used were made in the winter months. The blood of *Carcinus* was obtained by puncture of the articulations.

In all cases, the blood was dialysed against distilled water, changed twice daily, for about 8 days. As a general rule, a whitish deposit of protein was obtained after about a week's dialysis. It was found that this deposit contains only traces of copper, and it is therefore not haemocyanin. In preparations from the blood of crustaceans, this precipitate contains the orange carotenoid astacin (tetronerythrin), which is sometimes present in quantity.

When the first deposit of protein and other impurities was obtained, the supernatant material was transferred to a new membrane and dialysis was continued. An additional precipitation of impurities sometimes took place, in which case the material was again transferred to another membrane. The solution was not considered to contain pure haemocyanin unless it remained absolutely limpid for at least 8 days. At the end of 3 to 10 weeks, the pigment deposited in the crystalline state in the case of *Helix*, and in crystals mixed with amorphous matter in the case of *Octopus* and of *Carcinus*. In a few experiments instead of waiting for spontaneous crystallisation, the protein was brought to the isoelectric point by the addition of  $N/40$  HCl, drop by drop, with continuous stirring. If dialysis were then continued for some weeks, it was possible to obtain abundant deposits of haemocyanin.

The contents of the membranes were centrifuged when a sufficient amount of haemocyanin was obtained. The purified protein was then dissolved in  $M/15$  Sorensen phosphate buffer, usually at  $p_H$  7.5; concentrated solutions, up to 10% of protein, could be prepared in this manner.

(c) Thrice crystallised haemocyanin. The once crystallised material was washed with water on the centrifuge, dissolved by the addition of sodium chloride, as described in detail by Dhéré and by Burdel [1922], reprecipitated by dialysis, rewashed and redissolved and finally reprecipitated by dialysis and dissolved in phosphate buffer.

## 2. Experimental methods for measuring the distribution of proteins in a gravitational field.

Perrin [1908] devised methods for the determination of the distribution of microscopic or ultramicroscopic particles over short distances in a gravitational field. Burton [1922] and Porter and Hedges [1922] have made observations over longer distances (0.5 to 90 cm.) and concluded that there are forces acting between the particles which prevent the application of the simple formulae given by Perrin. Svedberg [1928] has criticised the methods of Burton and of Porter and Hedges, drawing attention to the difficulty of obtaining equilibria in long tubes. It may be noted that earlier work with his ultracentrifuge, using long tubes, was unsuccessful, and in the present form the distances are of the order of 5 mm. In the case of proteins, the theoretical formulae given by Adair [1935] indicate that distances of 2 cm. or more are required to produce measurable differences of concentration in a gravitational field.

Preliminary experiments with globulin (unpublished) indicated that the difficulties inherent in the use of long tubes could be, in some respects, eliminated

by the use of a system of the type shown in Fig. 1, where a cylindrical collodion membrane is filled with protein solution and placed in a tube of dialysate. In this apparatus, equilibration may take place by diffusion and sedimentation along the axis of the tube, as in the apparatus used by previous investigators, but in addition, the approximation to the equilibrium distribution may be facilitated by the movement of solvent across the membrane.

A solution of uniform composition with a density greater than that of the solvent is not in osmotic equilibrium, because the difference in densities of columns of protein solution and dialysate should lead to a difference in osmotic pressure and therefore solvent should flow out in the lower part of the membrane, causing an increase in concentration, to correspond with the higher pressure. At the same time, solvent should flow in and reduce the concentration of protein in the upper part of the column.

It is probable that, if a cell with two walls of glass or quartz were used, the most accurate method of determining the concentration gradient would be by the use of an interferometer, whereby the concentration of the protein at different depths could be estimated and the process of equilibration followed by taking readings on successive days. In the absence of an optical device of sufficient accuracy, a preliminary investigation has been made by leaving the protein solutions contained in cylindrical collodion membranes to equilibrate for a given time and then withdrawing samples from different depths for analysis, as described below. The measurements of the concentration gradient were combined with measurements of osmotic pressures which were made by a modification of the procedure described by Adair [1925].

The collodion membranes, from 5 to 20 cm. in length, were prepared by pouring 3 coats of collodion over rotating glass moulds of approximately 1.13 cm. diameter, giving membranes of capacity 1 ml. per cm. of length. The membranes were mounted on 3 cm. lengths of pressure tubing, slightly distended by a short length of glass tube shown in Fig. 1. The permeability of the membranes was adjusted so that at a pressure of 450 mm. mercury, approximately 0.01 ml. water per cm. of length flows out in one minute. The membranes were filled with haemocyanin solution dissolved in *M*/15 Sørensen phosphate buffer mixtures and attached to glass tubes of external diameter 6 mm. and internal diameter 1.4 to 3 mm. graduated in cm. and mm. The membranes were then fixed in tubes of buffer solution as shown in the figure. The temperature was regulated at 0° by placing the tubes in thermos flasks containing ice and water, which were kept in a refrigerator.

The level of the solution in the manometer was read daily for periods from 7 to 30 days, and in most cases the level was reset at a higher or lower point to see if the same pressure was reattained. After equilibration, the levels of the protein solution and of the dialysate, marked  $h$  and  $y_0$  respectively in Fig. 1, were

Fig. 1. Apparatus for measurement of osmotic pressure and concentration of protein at different depths,  $h$  = height of protein solution in manometer;  $y$  = level of dialysate. Rigid collodion membrane enclosing haemocyanin solution indicated by broken line.

read with an accuracy of 0.02 cm. on the glass scale. The distance between  $y_0$  and  $y_1$ , the end of the rubber tube, was estimated with an accuracy of 0.05 cm. with a ruler. The collodion tube was then lifted out of the dialysate, detached from the manometer and secured by a clamp at the point where the rubber tube is made rigid by the short glass tube. A sample of protein solution down to the level  $y_2$  (a few mm. below the edge of the rubber) was then removed and used for the measurement of the capillarity correction. The rigidity of collodion membranes made by the method referred to above is sufficiently great for them to be lifted out of the dialysate without appreciable distortion, and it was therefore possible to estimate the depth of the solution at  $y_2$  (defined as the distance between  $y_0$ , the surface of the dialysate, and  $y_2$ ) as the sum of the distance between  $y_0$  and  $y_1$ , measured with the membrane in the dialysate and the distance between  $y_1$  and  $y_2$ , measured with the membrane exposed to the air.

A capillary pipette, secured in a clamp, was then dipped into the solution and a sample down to the depth  $y_3$ , about 4 cm. below  $y_2$ , was removed very slowly by suction, controlled by a rubber tube and a glass tap. It is impossible to avoid all disturbance of the column, and uniformity of all details of procedure is desirable, so that as far as possible, the errors due to admixture with relatively light solution initially above  $y_2$  and with the relatively heavy solution initially below  $y_3$  cancel out. The sample from  $y_2$  to  $y_3$  was transferred to a refractometer beaker and mixed by means of the capillary pipette. Similar samples from  $y_3$  to  $y_4$  and from  $y_4$  to  $y_5$  were obtained by the same method. The refractive indices of the dialysate and of all the samples were determined by means of the Zeiss dipping refractometer. In a few experiments, the nitrogen content of individual samples was determined by the method of Kjeldahl. As a general rule, the samples from the refractometer beakers were afterwards pooled and the mixture used for measurements of nitrogen, density and refractive index.

### 3. Relationship between refractions, concentrations and densities of haemocyanin solutions.

In this work, the calculations of the protein concentration from nitrogen determinations were based on the values for the nitrogen content of the dry protein given by Roche [1934] and quoted in Table I. The refractive indices of protein solutions equilibrated with phosphate buffers have been discussed theoretically by Adair and Robinson [1930, 1]. Their measurements showed that under these conditions, the refractive indices of solutions of serum albumin and globulin are directly proportional to the protein concentration  $C$ , calculated from nitrogen determinations. In the present work, it was found that the refractive index of the solutions of haemocyanin was directly proportional to the concentration up to 10%, and it follows that the concentration can be calculated by the simple formula No. 1.

$$C = (R' - R'') \left( \frac{1}{\alpha'} \right) \quad \dots\dots(1),$$

$C$  = g. dry protein per 100 ml. solution;  $R'$  = refractive index of protein solution;  $R''$  = refractive index of dialysate;  $\alpha'$  = an empirical constant, equal to the refraction differences  $(R' - R'')$  for a 1% solution.

It may be noted that Redfield's [1934] value of 0.00198 for the specific refraction increment of *Limulus* haemocyanin dissolved in water exceeds the values for  $\alpha'$  given in Table I. The difference is not due to accidental errors; in the case of *Helix*, for example, where in a series of 9 determinations the maximum and minimum values are 0.00186 and 0.00175 respectively, the probable error of the

mean (0.00179) is less than 0.00001. One factor which may cause differences between  $\alpha'$  and the specific refraction increment for aqueous solutions is the ionisation of the proteins and the unequal distribution of salts across the membrane.

Table I. *Nitrogen content, refraction increments and density coefficients of haemocyanins equilibrated at 0° with M/15 phosphate buffer, p<sub>H</sub> 7.5.*

Species	<i>Helix</i>	<i>Octopus</i>	<i>Carcinus</i>
Nitrogen percentage of dry protein [Roche, 1934]	15.22	16.09	16.83
$\alpha'$ (Formula 1)	0.00179	0.00184	0.00187
$1/\alpha'$	559.0	543.0	535.0
$k$ (Formula 2)	0.27	0.27	0.27

The measurements of densities recorded in Fig. 2 show that there is a straight line relationship between density and the concentration  $C$ , as stated in the empirical formula No. 2.

$$D' = D'' + kC/100 \quad \dots\dots(2).$$

The percentage error in this series of measurements of densities was greater than in the measurements of refractive indices, and the constant  $k$  could not be estimated to more than 2 significant figures. The values for different species are given in Table I.

Fig. 2. Densities at 0° of solutions of haemocyanin equilibrated with M/15 phosphate buffer, p<sub>H</sub> 7.5, density 1.009. Circles, *Helix*; squares, *Octopus*; crosses, *Carcinus*.

#### 4. Measurements of the distribution of haemocyanin in a gravitational field.

The concentrations of samples of haemocyanin from different depths are recorded in Table II. The calculations of concentrations and ratios have been made and recorded to at least one decimal place more than the accuracy of the measurements of refractive index and other data. The values of the ratio  $C_2/C_1$  in the sixth column represent the concentration of the second sample divided by the concentration of the first sample. The values for  $C_2/C_1$  for different experiments are not strictly comparable, because the mean depths are not identical. In the seventh column the observed values have been used to calculate the value of the ratio  $C_2/C_1$  on the assumptions that the difference in depth between the first and second samples is 1 cm. and that the increase in  $C_2$  is proportional to the depth over the range investigated.

Table II. *Increase of concentration of haemocyanin with depth in a gravitational field.*

Letters H, O and C denote *Helix*, *Octopus* and *Carcinus* respectively. Dialysate *M*/15 phosphate buffer,  $p_H$  7.5, except for H 2 and H 7, which were at  $p_H$  6.8, and H 8, which was blood of *Helix* with dialysate 0.1435 *M* NaCl, 0.0087 *M* KCl, 0.0159 *M* CaCl<sub>2</sub>, 0.0428 *M* MgCl<sub>2</sub> [Arvanitaki and Cardot, 1932]. C 30 *Carcinus* blood.

Species and exp. no.	Mean depth. First sample	Mean depth. Second sample	Concentration. First sample	Concentration. Second sample	Ratio $C_2/C_1$	Ratio for 1 cm.
H 3	7.39	10.52	6.142	6.246	1.0170	1.0051
H 4	8.05	11.88	4.335	4.407	1.0166	1.0043
H 5	8.65	11.88	3.435	3.496	1.0178	1.0055
H 7	8.35	11.43	3.513	3.715	1.0576	1.0187
H 2	7.68	10.38	2.624	2.733	1.0417	1.0154
H 8	8.93	12.88	2.922	3.019	1.0333	1.0084
H 8	12.88	17.58	3.019	3.161	1.0470	1.0100
O 20	8.67	11.99	8.985	9.152	1.0186	1.0056
C 11	8.19	11.87	3.192	3.233	1.0128	1.0035
C 12	8.35	11.71	3.269	3.328	1.0181	1.0054
C 14	6.95	10.31	8.134	8.351	1.0267	1.0080
C 30	6.15	10.20	4.129	4.160	1.0075	1.0019
C 30	10.20	14.90	4.160	4.222	1.0015	1.0032

In the series of experiments on *Helix* haemocyanin, marked H, which were equilibrated for periods from 10 to 16 days, the ratio varied from 1.004 to 1.019. In the experiments on *Octopus* and on *Carcinus* haemocyanins, marked O and C respectively, carried out later, the times of equilibration were increased to about 25 days. The ratios show a range of variation from 1.002 to 1.008. It may be noted that the chief sources of error, including imperfect equilibration and accidental disturbances in taking the sample, tend to give low values for the ratio.

##### 5. The estimation of the osmotic pressure of haemocyanin.

In the majority of protein solutions, the osmotic pressure can be calculated with sufficient accuracy by the formula (3).

$$p_0 = \frac{10D'}{13.595} (h - x) \quad \dots\dots(3),$$

$p_0$  = osmotic pressure in mm. mercury at 0°, measured in a membrane permeable by electrolytes but impermeable by the protein;  $D'$  = density of the solution; 13.595 = density of mercury;  $h$  = observed height of column of solution expressed in cm. solution;  $x$  = rise due to capillarity.

It will be noted that  $p_0$  represents the osmotic pressure in the protein solution at the point  $y_0$  in Fig. 1, where the depth of the dialysate is equal to 0. At a point  $y$  cm. below  $y_0$  the protein solution is subjected to a higher pressure on account of its greater density, and the total osmotic pressure  $p$  at the depth  $y$  is given by formula (4), which is exact.

$$p = p_0 + \frac{10}{13.595} \int_0^y (D' - D'') dy \quad \dots\dots(4).$$

In the majority of protein solutions, the integral is small in comparison with  $p_0$ , but in the case of haemocyanin, the integral is of greater importance, as shown by the data in Table III, obtained for a specimen of snail's blood (Exp. 8). The densities at different depths recorded in the table were calculated by applying formula (2) to the measurements of concentration computed from refractive

Table III. *Osmotic pressures, Exp. H 8, calculated by formulae (4) and (5).*

Depth	Concentration	$(D' - D'')$	$p$ (formula 4)	$p$ (formula 5)
0	2.682	0.0072	0.358	0.358
8.93	2.922	0.0079	0.408	0.405
12.88	3.019	0.0082	0.431	0.426
17.58	3.161	0.0085	0.460	0.451

indices. The value for zero depth was estimated by extrapolation. It will be observed that the density difference  $(D' - D'')$  given in column 3 does not increase very rapidly with the depth, and it follows that the pressure calculated by formula (5) must be approximately equal to the exact value given by formula (4).

$$p = p_0 + \frac{10}{13.595} (D' - D'') y \quad \dots\dots(5).$$

In formula (5),  $y$  is equal to the mean depth of the sample taken for analysis and  $D'$  is the density of the sample. The range of error involved is small, as shown by the figures in the fifth column of Table III, where  $p$  has been calculated without making any allowance for the increase in  $(D' - D'')$  below the point where  $y = 0$ . It will be seen that the pressure  $p$  may be about 28% greater than  $p_0$  calculated by formula (3), in the case of the haemocyanin of the snail. Similar calculations of the proportion of the total pressure due to the term  $(D' - D'') y$  can be made from the experimental data recorded in Tables II and VII.

#### 6. Relationship between the osmotic pressure and the protein concentration.

In a previous paper [Roche *et al.*, 1932] two different methods of stating the composition of protein solutions were described, namely, the "corrected percentage concentration", symbolised  $C_p$ , expressed in g. dry protein per 100 ml. solvent, and the concentration, symbolised  $C$ , expressed in g. dry protein per 100 ml. protein solution. The theoretical treatment of the distribution of haemocyanin in a gravitational field may be simplified as described in the following section 7 by the use of the term  $C$  rather than  $C_p$ , because the densities of the solutions are directly proportional to  $C$  as stated in formula (2) and the correlation of such measurements with determinations of osmotic pressure is facilitated by the use of  $C$  rather than of  $C_p$ .

The curves in Fig. 3 show the relationship between the osmotic pressure and the concentration  $C$  when the haemocyanins prepared from the blood of the snail, the octopus and the crab are equilibrated with  $M/15$  phosphate buffers of  $p_H$  7.4 and 7.5 at  $0^\circ$ . It may be noted that the pressures are extremely small, especially in the more dilute solutions. In spite of the difficulties inherent in the measurements of low pressures, and of the additional term in the calculations of pressures defined by formula (5), the points lie close to the smooth curves shown in the figure. The points shown in this figure do not give a complete record of the data for *Helix*. One additional series of measurements made at  $p_H$  6.8 is summarised in Table IV. The difference between the osmotic pressures at  $p_H$  6.8 and 7.5 seems to be less than 0.1 mm.

In four experiments on the whole blood of *Helix*, at  $p_H$  7.5, containing about 3.09% haemocyanin, the values of the ratio  $p/C = \pi$  were 0.15, 0.30, 0.21 and 0.22 respectively. These values are of the same order as those obtained for crystallised haemocyanin, and it may be inferred that the process of purification does not cause great changes in the structure of the molecules. Further evidence on this point was obtained in an experiment on crab's blood at  $p_H$  7.4, where the pressure of 1.47 mm. at a concentration  $C = 4.06$  is in agreement with the curve for purified haemocyanin, shown in Fig. 3. The results recorded in Table V

1	3.41	0.35	0.10
7	3.62	0.32	0.08
58	3.49	0.31	0.09
59	3.16	0.41	0.13

Table V. Osmotic pressure and membrane potentials of thrice crystallised haemocyanin at  $p_H$  7.4.

$E$  = potential in m.v. at 0°;  $p_i$  = calculated pressure of diffusible ions.

Exp. no.	Animal	$C$	$E$	$p_i$ (calc.)	$p$ (observed)
1 (3)	<i>Octopus</i>	3.55	-0.44	1.03	1.02
2 (3)	<i>Octopus</i>	2.84	-0.36	0.69	0.54
3 (3)	<i>Helix</i>	1.96	-0.23	0.28	0.30
4 (3)	<i>Helix</i>	0.90	-0.19	—	0.06

show that material subjected to three crystallisations gives pressures similar to those obtained with material once crystallised.

The relationship between the osmotic pressure  $p$ , expressed in mm. mercury at 0°, and the molecular weight is formulated below:

$$p = RT\phi c_p = RT\phi \frac{10C}{M} = 170,330\phi \left(\frac{C}{M}\right) \quad \dots\dots(6),$$

where  $T$  = absolute temperature;  $R$  = gas constant. At  $0^\circ$ ,  $RT$  = product of pressure and volume of 1 g. mol. of a perfect gas = 760 mm.  $\times$  22.414 litres = 17,033;  $c_p$  = g. mol. protein per litre protein solution;  $M$  = molecular weight, or the mean molecular weight if the protein be polydisperse;  $\phi$  = a coefficient, equal to the ratio  $p/RTc_p$ .

The term  $\phi$  represents the sum of the osmotic effects due to three factors: (1) the volume occupied by the protein hydrate, (2) the "partial pressure" symbolised  $p_i$ , due to the excess of diffusible ions inside the membrane, referred to in Donnan's theory and (3) attractive and repulsive forces between the protein particles. Previous investigations on haemoglobin [Adair, 1928] and serum proteins [Adair and Robinson, 1930, 2] have shown that  $\phi$  approaches unity at low protein concentrations, so that accurate values of molecular weights can be determined by extrapolation. In the case of haemocyanin, the osmotic pressures of the dilute solutions are so small that the application of methods of extrapolation must be postponed.

Table VI includes a series of values of the ratio  $M/\phi$  which is equal to  $10RTC/p$  calculated from the curves shown in Fig. 3. It will be seen that this ratio diminishes with increasing concentrations, in accordance with observations on haemoglobin and on serum proteins referred to above, which shows that  $\phi$  is greater than unity even in the case of 3% solutions, and it may be inferred that the molecular weights of the haemocyanins are greater than the values for such solutions entered in the second column of Table VI.

Table VI. Values of the ratio  $M/\phi$  at different concentrations of haemocyanin.

Animal	$C = 3.0$	$C = 6.0$	$C = 9.0$
<i>Helix</i>	1,800,000	1,400,000	—
<i>Octopus</i>	710,000	630,000	570,000
<i>Carcinus</i>	550,000	440,000	330,000

The values obtained by the osmotic method are comparable with ultracentrifugal measurements. The sedimentation velocity of the haemocyanin of *Carcinus*, recorded by Svedberg [1933] corresponds to a molecular weight of  $620,000 \pm 40,000$ , a figure rather larger than  $M/\phi = 550,000$  estimated by the osmotic method, but it is obvious from the data in Table VI that  $M/\phi$  tends to increase with dilution, and a value of  $M = 620,000$  is consistent with the osmotic measurements. In the case of the haemocyanin of *Octopus*, the measurements of sedimentation velocity made by Svedberg and Eriksson [1932] show that the molecular weight depends upon the  $p_H$  value. In certain ranges the molecular weight is about 2,000,000, but at  $p_H$  7.5 the mean molecular weight may be about one-fifth of this value ( $400,000 \pm 150,000$ ), a figure which is below the value  $M/\phi = 710,000$  obtained by the osmotic method. It is not unlikely that the difference may be accounted for by the fact that the centrifugal measurements are made on dilute (0.5%) solutions at  $20^\circ$ , whereas the osmotic measurements were made on more concentrated solutions at  $0^\circ$ .

In the case of the haemocyanin of *Helix*, which has been studied in detail by ultracentrifugal methods, the molecular weight is 5,100,000, a value more than three times as great as  $M/\phi$  estimated by osmotic methods. One possible explanation of the difference is the pressure due to the excess of diffusible ions inside the membrane, symbolised  $p_i$ . Calculations of  $p_i$  have been made as described by Adair and Robinson [1930, 2] and recorded in Table V. It appears that the effect of the term  $p_i$  must be balanced by interionic attractions, because the observed pressures for concentrated solutions are lower than the

(extrapolated) values for  $p_i$ . Osmotic abnormalities of this type were observed by Hammarsten [1924] and have been discussed thermodynamically by Linderstrøm-Lang [1926]. In the circumstances, it is by no means certain that the discrepancy can be accounted for by the term  $p_i$ .

In the case of a substance of molecular weight 5,100,000 the presence of relatively small amounts of less polymerised particles may cause marked alterations in the mean molecular weight, and it is not unlikely that the relatively low value of 1,800,000 for  $M/\phi$  is partly due to the polydisperse state of the solution. In experiments where chloroform was added as a preservative,  $M/\phi$  was reduced to 700,000, an observation which suggests that the haemocyanin of *Helix* tends to form degradation products.

### 7. Theoretical calculation of the distribution of a protein in a gravitational field from measurements of osmotic pressure.

In the system shown in Fig. 1, where the density of the protein solution  $D'$  is greater than that of the dialysate, symbolised  $D''$ , an increase in the depth must be correlated with an increase in the osmotic pressure, which is defined as the difference between the hydrostatic pressure in the colloidal solution and the dialysate.

$$dP = (D' - D'') dy \quad \text{.....(7),}$$

where  $dP$  = increase in osmotic pressure, expressed in cm. water of density 1.00.

In the gravitational field, the hydrostatic pressure and composition of the dialysate may change slightly with depth, but the effects of these changes must be small, and the terms  $P$ ,  $D'$  and  $D''$  in formula (7) should agree with measurements made using solutions with different protein concentrations equilibrated with a dialysate of constant pressure and composition.

The term  $(D' - D'')$  is then equal to  $kC/100$ , as stated in formula (2);  $k = 0.27$ , in solutions of haemocyanin equilibrated with the standard phosphate buffer mixtures. The pressure  $p$ , in mm. mercury, is given by formula (6):

$$p = RT\phi (10C/M),$$

where  $RT = 17,033$  at  $0^\circ$ . If the pressure  $P$  be expressed in cm. water,  $RT$  must be given in the same units, and it follows that  $P = 23,158\phi (10C/M)$ .

Using the values for pressures and densities given above, formula (4) can be restated in terms of the concentration  $C$ .

$$\frac{10RT}{M} d(\phi C) = \frac{kC}{100} dy \quad \text{.....(8).}$$

The integration of this formula, allowing for the variation of  $\phi$  with concentration, has been described by Adair [1935]. In the special cases where  $C_l$ , the concentration of the lower sample at the depth  $y_l$ , is only slightly greater than  $C_u$ , the concentration of the upper sample at the depth  $y_u$ , the change in  $\phi$  is small, and the ratio  $C_l/C_u$  may be calculated by the approximate formulae (9) and (10):

$$\int \frac{dC}{C} = \ln \frac{C_l}{C_u} = \frac{M\phi^{-1}k(y_l - y_u)}{1000RT} \quad \text{.....(9),}$$

$$\frac{C_l}{C_u} = \exp. \left( \frac{M\phi^{-1}(y_l - y_u)}{85.8 \cdot 10^{-6}} \right) = \left[ 1 + \frac{M\phi^{-1}(y_l - y_u)}{85.8 \cdot 10^{-6}} \right] \quad \text{.....(10).}$$

If the solutions be as dilute as those used by Svedberg, 0.1 to 0.5%, the term  $\phi$  should approach unity, and the ratio  $C_l/C_u$  can be calculated from the molecular weight. If  $M$  be equal to 5,100,000, as in the case of *Helix*, the ratio should be approximately 1.059 for an increase in depth of 1 cm. The ratio

diminishes to 1.006 for a molecular weight of 500,000. The observed ratios given in the last column of Table VII are lower than these calculated values, but the experiments were made at much higher protein concentrations, at which  $\phi$  is greater than unity, as shown by the measurements of osmotic pressure recorded in Table VII, column 3.

Table VII. *Comparison of observed increase of concentration of haemocyanin with depth and values calculated from osmotic pressure measurements.*

Exp. no.	$C$	$p$	$M/\phi$	Ratio calculated	Ratio observed
H 3	6.35	0.85	1,260,000	1.0146	1.0051
H 4	4.48	0.49	1,550,000	1.0180	1.0043
H 5	3.55	0.22	2,700,000	1.0314	1.0055
H 7	3.63	0.32	1,950,000	1.0227	1.0187
H 8	3.09	0.44	1,100,000	1.0128	1.0084
O 20	8.88	2.56	590,000	1.0068	1.0056
C 11	3.20	1.06	510,000	1.0059	1.0035
C 12	3.33	1.25	450,000	1.0052	1.0054
C 14	8.17	3.71	370,000	1.0043	1.0080
C 30	4.06	1.46	470,000	1.0055	1.0019

The values of  $M/\phi$  calculated from measurements of osmotic pressure are given in column 4. The ratios in column 5 are calculated from these measurements by formula (10). Considering the technical difficulties of measuring small pressures and small differences in concentrations, the agreement between the observed and the calculated values is within the limits of experimental error, in the case of the observations on *Octopus* and *Carcinus*. In a number of the experiments on *Helix*, the observed ratio is much lower than that calculated. It must be remembered that the observed ratios in Table VII represent the distribution of the protein at the time the osmometer was taken down, and the chief object of the comparison of the observed and calculated results was not to test the validity of formula (10) but to use the formula as a test for the existence of a state of equilibrium. In the circumstances it may be inferred that although a number of the osmometers containing the haemocyanin of *Helix* failed to reach a state of equilibrium, the osmometers containing *Octopus* and *Carcinus* haemocyanin, which were allowed to equilibrate for a longer period (up to 25 days) gave an approximation to the equilibrium distribution within the limits of experimental error.

#### SUMMARY.

A method is described for the preparation and recrystallisation of haemocyanin.

Measurements are recorded of the osmotic pressures of haemocyanins prepared from the blood of *Helix pomatia*, *Carcinus moenas* and *Octopus vulgaris*.

The mean molecular weights of the haemocyanins, calculated from the osmotic data, are compared with those calculated by Svedberg from ultracentrifugal measurements.

A preliminary study has been made of the distribution of haemocyanin in a gravitational field.

# CCCIX. THE REVERSIBLE INHIBITION OF $\beta$ -MALT-AMYLASE BY ASCORBIC ACID AND RELATED COMPOUNDS.

By CHARLES SAMUEL HANES.<sup>1</sup>

*From the Ontario Research Foundation, Toronto, Canada.*

*(Received September 30th, 1935.)*

THE activities of several enzymes appear to be markedly influenced by reduced ascorbic acid. Papain is reported to be inhibited by ascorbic acid alone but activated by ascorbic acid *plus* ferrous sulphate [Maschmann and Helmert, 1934]. Cathepsin is activated by ascorbic acid and the activation is increased by the presence of iron [Euler *et al.*, 1934]. An activation is also reported for arginase [Edlbacher and Leuthardt, 1933]. Inhibitions have been reported in the cases of urease [Edlbacher and Leuthardt, 1933] and  $\beta$ -malt-amylase [Purr, 1934].

In the present investigation the observation of Purr that  $\beta$ -malt-amylase is strongly inhibited by reduced ascorbic acid has been confirmed. Moreover, evidence has been found which suggests that the effect can be attributed to the presence of the dienol grouping in the vitamin and that it is not due merely to the reducing properties of this grouping, since (1) two other dienol compounds, dihydroxymaleic acid and reductone, exert the same type of inhibition, and (2) the inhibition by a dienol compound is reversed not only by oxidative destruction of the dienol grouping but also by the addition of a variety of other reducing substances including hydrogen cyanide, sodium hydrosulphite and several sulphydryl compounds. This latter effect, the reversal of dienol inhibition by other reagents of a reducing character, even though the actual mechanism of this reactivation remains obscure, would seem to exclude the possibility that the effect of the vitamin and the other dienol compounds is due merely to their reducing properties.

The results to be described thus suggest that the inhibitory action on  $\beta$ -malt-amylase is of the nature of a specific effect and they accordingly lend plausibility to the view that the vitamin function of ascorbic acid may be related to its ability to function as a regulator of enzyme activity within the cell.

## *Preparation of $\beta$ -malt-amylase.*

The enzyme was prepared from ungerminated barley by a method based on that of van Klinkenberg [1931]. The seed coat, aleurone layer and most of the embryonic tissue were removed from a specimen of high-grade malting barley by grinding in an abrasive mill. The product, which resembled commercial "Pearl Barley", was ground to a fine flour.

200 g. of the flour were extracted with 700 ml. 50 % ethyl alcohol for 2 hours. After centrifuging, the residue was again extracted with 250 ml. 50 % alcohol and again centrifuged down. The supernatant liquors were combined and the enzyme precipitated by the addition of alcohol to a final concentration of 80 %. The precipitate was removed on the centrifuge and washed once by re-suspension in 80 % alcohol. The washed residue was thoroughly drained on a suction filter

<sup>1</sup> Now at the Low Temperature Research Station, Cambridge.

and was then suspended in 200 ml. of water. An insoluble fraction was removed by filtration after 5 days.

Three such concentrated stock enzyme solutions (prepared from two different specimens of barley) were used in the present investigation, all of which gave similar results. The stock enzymes were stored under toluene at 0° in which conditions only slight changes in activity (less than 10 %) occurred in an 8-week period.

Portions of stock enzyme sufficient for 1 or 2 days' experiments were removed as required and after suitable dilution (6 to 10-fold in different cases) were stored in the reaction thermostat at 25°.

#### *Reagents.*

Conductivity water (from an all-pyrex still) was used in the preparation of enzyme, substrate and all reagents used in the pretreatment of the enzyme. Solutions used in pretreatment were adjusted to the natural acidity of the enzyme ( $p_H$  6.4) by appropriate additions of sodium hydroxide.

The following dienol compounds were used:

1. Ascorbic acid as supplied by British Drug Houses.
2. Glucoreductone ( $\text{CHO}:\text{COH}:\text{CHOH}$ ) was prepared from glucose by the method of Euler and Martius [1933]. The product after recrystallisation from acetone and ethyl acetate had properties in general agreement with the description of these authors although no claim can be made for its absolute purity, as will be clear from the following observations: mol. wt. from the rise of boiling point in acetone solution (Pregl method), 90, 99, 93, average 94; acid equivalent, 87.5; iodine equivalent, 92.
3. Dihydroxymaleic acid ( $\text{HOOC}:\text{COH}:\text{COH}:\text{COOH}$ ) was prepared from tartaric acid by the procedure of Fenton [1905], solid carbon dioxide and acetone being used as a refrigerant during the oxidation with hydrogen peroxide. The anhydrous substance gave theoretical values for titratable acidity and iodine consumption. In some experiments the disodium salt of this acid (prepared by neutralising an alcoholic solution of the acid with alcoholic sodium hydroxide) was used.

Solutions of the dienol compounds were freshly prepared a short time (rarely more than 20 min.) before mixing with the enzyme. Sodium hydrosulphite was used within 2 min. of dissolving. Other reagents, hydrogen cyanide, sulphhydryl compounds *etc.*, were prepared daily.

The various reducing compounds in the low final concentrations in which they occurred in the starch digests were found to have no appreciable influence on the determination of maltose production in the digests of starch.

#### *Procedure for pretreatment of enzyme and activity determinations.*

Throughout the investigation a standard volume of 2 ml. of enzyme (containing from 0.8 to 1.4 mg. dry matter) has been used. Pretreatment of the enzyme with the various reagents studied has usually been carried out individually on these standard 2 ml. portions contained in small vials supported in the bath at 25°, although in some experiments it was more convenient to pretreat a larger volume from which a number of samples (equivalent in volume to 2 ml. of the original) were taken for activity determination.

Activity values are based on determinations of the initial velocity of maltose production in digests of soluble starch at 25° and  $p_H$  4.7 (the optimum value). The standard volume of enzyme, diluted to 5 ml. by the addition of water or reagents used in pretreatment, is added from the vial to a digest flask, the lip of

the vial being first lightly smeared with vaseline. The digest flask contains 25 ml. 0.66% soluble starch (saturated with toluene) and 3 ml. *N*/5 acetate buffer of  $p_{\text{H}}$  4.7.<sup>1</sup> The vial is rapidly rinsed with the reaction mixture and thereafter 5 ml. samples are removed at intervals for maltose determination by the methods described earlier [Hanes, 1929; 1932]. The first sample is taken at 0.7 min. and subsequent samples usually at intervals of 1.2 min. In most experiments four samples were taken from each digest, the observations being thus restricted to the first 5–6 min. of the reaction.

It has been shown earlier [Hanes, 1932] that under these conditions the progress curves of maltose production normally remain almost linear, there being only a small decrease in the reaction velocity during the short period under observation. This has been found to hold true in the present study for digests with untreated enzyme, or enzyme reactivated after diol inhibition. With inhibited enzyme, however (particularly after pretreatments with ascorbic acid and reductone), the rate of maltose production frequently falls off with somewhat variable rapidity which indicates a further development of the inhibition after the enzyme (with diol compound) is added to the buffered substrate. At least part of this increased inhibition results from the presence of the more acid buffer of the digest, but the presence of heavy metal impurities with the starch may also contribute (*v. p.* 2599). This feature has the effect of increasing the experimental error in deriving initial slope values with inhibited enzyme, but the initial slope method clearly remains the most desirable basis of assessing activity as it provides as nearly as possible a measure of the activity of the enzyme at the termination of its controlled pretreatment. Examples of progress curve data will be seen in Table V. and in Fig. 5.

#### EXPERIMENTAL.

##### *The time course of the diol inhibition.*

(a) *Development.* In a number of experiments in which the rate of development of inhibition was followed it became clear that the effect was not "instantaneous" but (except with very low concentrations of inhibitor) required a period of several minutes for maximum development. This will be sufficiently illustrated by the graphs of Fig. 1 in which the observed inhibitions are plotted against duration of pretreatment with what may be termed high, medium and low amounts of reduced ascorbic acid—2.5, 0.1 and 0.03 mg. respectively per standard volume (2 ml.) of enzyme. In these cases the ascorbic acid in 1 ml. of solution was added to 2 ml. of enzyme for the pretreatment, 2 ml. of water being added immediately before starting the digest.

Data from three different experiments with 0.1 mg. ascorbic acid have been plotted to illustrate the degree of reproducibility of the results. They would indicate a maximum inhibition of about 80% developing in 10–15 min. With 2.5 mg. ascorbic acid the full inhibition of 98% had developed within 7 min.<sup>2</sup> Only with the lowest amount of ascorbic acid (0.03 mg.) does the earliest activity determination (after 1 min. pretreatment) show maximum inhibition. In this case the subsequent determinations show that the inhibition becomes progressively smaller.

<sup>1</sup> The final volume of the standard digest is thus 33 ml. and the starch concentration 0.50%. For substrate we find most suitable potato starch "solubilised" according to the procedure of Small [1919]. The moisture content is determined by drying to constant weight at 110° in a high vacuum in the presence of  $\text{P}_2\text{O}_5$ .

<sup>2</sup> With intermediate doses 0.2–0.7 mg. a slight progressive increase in inhibition has been observed for periods up to 5 hours. An example is shown in Fig. 2.

(b) "*Spontaneous*" regeneration after diénol inhibition. The phenomenon of regeneration of activity, which is noticeable in the inhibition-time curve with low ascorbic acid in Fig. 1, has been investigated in some detail and has been found to be associated with the destruction of the inhibiting diénol group by aerobic oxidation. With increasing amounts of inhibitor, regeneration is slower in appearing and smaller in extent. We give in Table 1 observations extending over longer periods which illustrate the magnitude of the effect with different concentrations of ascorbic acid.

Fig. 1. The time course of inhibition by three concentrations of ascorbic acid, 0.03, 0.1 and 2.5 mg. respectively, in 1 ml. added to 2 ml. enzyme. Observations from three experiments with the intermediate concentration are shown.

Table 1. *Regeneration of activity during prolonged ascorbic acid treatment.*

2 ml. enzyme pretreated with 1 ml. ascorbic acid solution.

mg. ascorbic acid in 1 ml.	Relative activity after pretreatment for		
	1 hour	20 hours	45 hours
0.1	21	44	--
0.2	12	36	51
0.7	4	16	22

The elucidation of this feature has brought to light an interesting difference in the behaviour of the three diénol compounds, in that the regeneration of activity during treatment with ascorbic acid is much slower than with dihydroxymaleic acid or reductone.

Experiments were carried out in which the activity of the enzyme and the degree of oxidation of the diénol compound mixed with it were followed simultaneously. For the latter determination 5 ml. samples of the enzyme-inhibitor solution were acidified with 2 ml. 5% acetic acid; an excess of iodine was added by pipette and back-titrated with sodium thiosulphate in the presence of 4 drops of 1% soluble starch. Under these conditions the enzyme alone showed no iodine consumption.

In Fig. 2 are given the results of such an experiment in which three portions of the same enzyme solution were treated with ascorbic acid, dihydroxymaleic acid and reductone of the same concentration. The pretreatment was carried out in each case by the addition of 40 ml. of  $M/800$  solution of the diénol compound

to 80 ml. of enzyme contained in a 500 ml. flask, the solutions being kept aerated by frequent whirling of the contents about the walls. Samples of 5 ml. for determination of iodine consumption and 3 ml. for activity determination were taken at intervals. In order to insure the same acidity in the three solutions, the dienol compounds after first neutralising to  $p_{\text{H}}$  6.4 with NaOH were made up to volume with the addition of phosphate buffer of this  $p_{\text{H}}$  to give a concentration of  $M/200$ . Accordingly the pretreatment of the enzyme was carried out in the presence of  $M/600$  phosphate of  $p_{\text{H}}$  6.4 and the final concentration of inhibitor was  $M/2400$  in each case.<sup>1</sup>

Fig. 2. The time course of inhibition (upper) and iodine-reducing capacity (lower) during treatments of the enzyme with  $M/2400$  ascorbic acid (*A*), reductone (*R*) and dihydroxymaleic acid (*M*).

In the upper part of Fig. 2 it will be seen that the enzyme treated with ascorbic acid showed a rapid fall in activity to approximately 3% of the original value, rising in the course of 5 hours to 7%. A subsequent determination at 24 hours (not shown) indicated a further regeneration to 32% of the original. In contrast to this effect it will be seen that the inhibitions by the two other dienol compounds were of a transient nature. The inhibition by reductone, initially of the same order as that by ascorbic acid, decreased very rapidly so that in 30 min. the activity had risen to 85% of the control value; after the rapid regeneration to this level the activity rose only very slowly, reaching 91.5% of the control value after 24 hours (not shown). A subsequent determination (32 hours) showed no further recovery. The dihydroxymaleic acid inhibition, considerably smaller initially than the others, also decreased rapidly and after 3 hours the activity was identical with that of the untreated control.

In the lower part of Fig. 2 are shown the iodine consumption data for the three enzyme-inhibitor mixtures expressed in ml. 0.004*N* iodine per 5 ml. In the ascorbic acid-enzyme mixture a relatively slow decrease in iodine consumption occurred. The value fell from 0.84 to 0.67 in 5 hours, and (not shown) to 0.415 after 23 hours. In the cases of the other dienol compounds, however, rapid

<sup>1</sup> For convenience in comparing with other treatments this corresponds to the addition of 1 ml. containing 0.22 mg. ascorbic acid, 0.185 mg. dihydroxymaleic acid and 0.11 mg. reductone, respectively, to the standard 2 ml. volume of enzyme.

oxidation of the dienol group occurs so that the iodine consumption values fall to zero in 1 hour with dihydroxymaleic acid and in 15 min. with reductone. It is noteworthy that the complete disappearance of the reducing group occurred in each case before the activity of the enzyme had regenerated to its maximum extent.

It is clear from the results of this experiment that the regeneration of the enzyme is closely correlated with the destruction of the inhibiting dienol group (probably by aerobic oxidation) and that the differences in duration of the inhibitions produced by the three substances are due to differences in the stability of the dienol group as it occurs in them.

Two further points in this experiment are worthy of note—namely that the iodine consumption values immediately after mixing enzyme and dienol solutions are appreciably lower than the theoretical values for the dienol alone, and that in the cases of reductone and dihydroxymaleic acid the complete oxidation of the dienol group occurs before the regeneration of the enzyme activity is complete. These points, which suggest that a small amount of the dienol compounds combines with some constituent of the enzyme preparation, are being further investigated.

Fig. 3. The time course of inhibition (upper) and iodine-reducing capacity (lower) during treatments with *M*/800 ascorbic acid and reductone.

We give in Fig. 3 the results of a similar experiment in which portions of enzyme were pretreated with *M*/750 (final concentration) ascorbic acid and reductone (slightly more than three times the strength used in the preceding experiment). This corresponds to the pretreatment of 2 ml. enzyme with 1 ml. containing 0.704 mg. ascorbic acid and 0.352 mg. reductone. As before the dienol compounds after neutralisation to  $p_H$  6.4 were dissolved in *M*/200 phosphate buffer of this  $p_H$ . The iodine consumption determinations were made on 3 ml. samples.

To facilitate comparison we have included in Fig. 3 the activity-progress curve for *M*/2400 reductone re-drawn from Fig. 2. It will be seen that the increased concentration of reductone resulted in a slightly greater initial inhibition and that the subsequent regeneration is considerably slower and less

complete. As before the determinations of iodine consumption indicate a rapid oxidation of reductone and a very slow oxidation of ascorbic acid. In contrast to the results of Fig. 2, however, the iodine consumption values did not fall to zero but after 100 min. treatment there remained a small residual reducing power which decreased extremely slowly.

*Effect of the enzyme preparation on the oxidation of the  
three dienol compounds.*

Experiments of the type just described led to a study of rates of oxidation of the three dienol compounds in the presence and absence of small amounts of the enzyme preparation. Mawson [1935] and others have reported that extracts of animal tissues possess the property of protecting ascorbic acid against aerobic oxidation. We have found that the  $\beta$ -amylase preparation, an extract of ungerminated barley, has a similar action in decreasing considerably the rate of oxidation of ascorbic acid. In contrast, however, to its stabilising action toward ascorbic acid the presence of the enzyme preparation markedly accelerates the oxidation of the other two dienol compounds.

The following experiment will serve to illustrate this difference in the action of the enzyme extract toward the three compounds.

$M/500$  solutions of ascorbic acid, reductone and dihydroxymaleic acid, neutralised to  $p_H$  6.4 with NaOH and made up in  $0.005 M$  phosphate of this same  $p_H$  were used. Within 1.5 min. of dissolving the dry substances in the previously measured NaOH and buffer (already diluted to volume) two 50 ml. portions of each dienol solution were treated as follows: to one were added 3 ml. of water, to the other 3 ml. of undiluted stock enzyme solution. Samples of 10 ml. were taken at intervals for determinations of iodine consumption in the manner described earlier (p. 2591). Throughout the experiment the solutions were aerated every 3 or 4 min. by whirling around the walls of the 500 ml. flasks in which they were contained. The final concentration of the dienol compounds was  $0.0185 M$  throughout (which is considerably stronger than in either of the two preceding inhibition experiments) and in the solutions to which enzyme extract was added the dry matter from the extract amounted to 0.28 mg. per ml. of the final solution (which is smaller than under the normal pretreatment conditions).

From the iodine consumption values the progress of oxidation of the dienol group in the six solutions was calculated: the results appear in Table II.

Table II. *Aerobic oxidation of dienol compounds in presence and  
absence of added enzyme preparation.*

Dienol compounds  $0.0185 M$  throughout;  $p_H$  6.4; temp. 21.5–22.5°.

Time min.	Percentage oxidation of dienol group					
	I Ascorbic acid		III Reductone		V Dihydroxymaleic acid	
	Alone	+ Extract	Alone	+ Extract	Alone	+ Extract
15	13.9	4.8	18.3	38.8	4.9	12.2
30	23.2	5.7	25.5	57.2	7.0	18.4
45	32.2	6.7	32.2	66.5	—	—
60	39.8	7.5	37.8	79.8	10.5	27.3
75	47.0	8.1	43.6	87.5	11.8	31.0
95	—	—	—	—	13.5	36.7

By comparing columns I, III and V it will be seen that in the absence of the enzyme extract dihydroxymaleic acid is oxidised least rapidly, ascorbic

acid and reductone being oxidised at considerably greater and roughly similar rates. (The initial rate for reductone is slightly higher but falls off appreciably.) With added extract, however, there is a marked change in the rates; ascorbic acid is oxidised much less rapidly than before, and the rate of oxidation of the other two compounds is considerably increased. Thus the addition of the extract has decreased the oxidation of ascorbic acid for the 75-min. period from 47 to 8.1%—whereas the oxidation of reductone is increased from 43.6 to 87.5% and that of dihydroxymaleic from 11.8 to 31.0%.

From results of this type it is concluded that the enzyme extract contains a factor (or factors) of unknown nature which protects the dienol group of ascorbic acid against aerobic oxidation, but that under the same conditions the oxidation of reductone and dihydroxymaleic acid is greatly accelerated. Further investigation is required before the nature of this effect can be discussed.

This peculiar difference in the behaviour of the three dienol compounds in the presence of the enzyme extract offers a clear explanation of the differences in the duration of their inhibitory action on  $\beta$ -amylase. Ascorbic acid which is stabilised against oxidation by the extract produces the most permanent inhibition, whereas reductone whose oxidation is most rapid in the presence of the extract produces the most transient inhibition, dihydroxymaleic acid being intermediate in both respects.<sup>1</sup>

*The effect of oxidisers dienol compounds and the addition of oxidants with the reduced compounds.*

As would be expected from the foregoing experiments the oxidation of the dienol compounds by aeration before mixing with the enzyme destroys their inhibitory power. The effects of 10-min. pretreatments with reduced and aerobically oxidised ascorbic acid and reductone are given in Table III.

Table III.

	Relative activity
2 ml. enzyme. Untreated control (initial velocity 0.320)	100
2 ml. enzyme + 1 ml. $\pm$ 0.2 mg. reduced ascorbic acid—10 min.	12
2 ml. enzyme + 1 ml. $\pm$ 0.2 mg. oxidised ascorbic acid*—10 min.	97.5
2 ml. enzyme + 1 ml. $\pm$ 0.1 mg. reduced reductone—10 min.	15
2 ml. enzyme + 1 ml. $\pm$ 0.1 mg. oxidised reductone†—10 min.	98

\* Solution previously aerated 48 hours. Iodine consumption 3% of original.

† Solution previously aerated 24 hours. Iodine consumption 1.5% of original.

Owing to the extreme sensitivity of  $\beta$ -malt-amylase to inactivation in the presence of slight traces of most oxidising reagents the choice of reagents other than molecular oxygen for the oxidation of the dienol group is limited. Pretreatment of the enzyme with ascorbic acid previously oxidised with iodine produces considerable inhibition although not as much as reduced ascorbic acid. For example, 5-min. treatments of 2 ml. enzyme with 0.35 mg. of reduced and

<sup>1</sup> The selective stabilisation of ascorbic acid by barley extracts seems of interest not only in connection with the present subject but also in suggesting a possible explanation of the specificity of ascorbic acid as an antiscorbutic factor. It seems possible that the failure of reductone and dihydroxymaleic acid to protect against scurvy (as reported by Euler and Martius [1933] and Dahlmer [1934] respectively) may be due to the accelerated oxidative destruction of these dienol compounds in the presence of tissues in contrast to ascorbic acid which is known to be protected against oxidation. This suggestion is being investigated with a wider range of dienol compounds than has hitherto been available and with a variety of plant and animal extracts.

iodine-oxidised ascorbic acid produced inhibitions of 82.5 and 53.5 % respectively. We are inclined to believe however that the inhibition in the latter case was due to traces of free iodine which in a concentration of  $3.3 \times 10^{-6} N$  would account for this effect.<sup>1</sup>

In an investigation of the effects of a variety of oxidation systems on  $\beta$ -malt-amylase (which will be described in a subsequent paper) it was found that potassium ferricyanide and methylene blue produce only very slow inactivation. We have accordingly tried the effect of adding these substances with reduced ascorbic acid during pretreatments of the enzyme. Typical results are given in Table IV.

Table IV. *Pretreatment with ascorbic acid in the presence of methylene blue and potassium ferricyanide.*

Enzyme, 2 ml.; ascorbic acid, 0.1 mg. in 1 ml.; methylene blue and potassium ferricyanide, 1 ml. of 0.001 M solution.	
	Relative activity
Enzyme. Untreated (initial velocity 0.405)	100
Enzyme + ascorbic acid. Pretreated 15 min.	22
Enzyme + ascorbic acid + methylene blue. Pretreated 15 min.	57
Enzyme + ferricyanide. Pretreated 15 min.	97
Enzyme + ascorbic acid + ferricyanide. Pretreated 15 min.	86.5
Enzyme + ascorbic acid + ferricyanide. Pretreated 25 min.	95

It will be seen that methylene blue (which oxidises ascorbic acid only slowly) decreases the inhibition appreciably and ferricyanide (which oxidises ascorbic acid moderately rapidly) almost entirely removes the inhibition.

It can be concluded from the results of the foregoing experiments that the strong inhibition of  $\beta$ -amylase is due to the reduced forms of the dienol compounds used. The regeneration of the activity of the enzyme observed is clearly associated with the aerobic oxidation of the inhibiting compound and it has been shown that treatment with the previously oxidised compounds produces no inhibition. Moreover, the presence of methylene blue and ferricyanide to a great extent prevents the inhibition.

Fig. 4. Relation between degree of inhibition and concentration of ascorbic acid. Pretreatment period 10 min. The indicated amounts of ascorbic acid dissolved in 1 ml. were added to 2 ml. enzyme.

<sup>1</sup> Such inhibition by iodine-oxidised ascorbic acid, unlike that by the reduced substance, is not reversed by treatment with cyanide or hydrosulphite. This is also true of inactivation by iodine.

*Relation between inhibition and concentration of ascorbic acid.*

In many experiments, particularly those of an exploratory nature, a pre-treatment period of 10 min. was used. Consequently, although no single experiment was designed to investigate the relationship between amount of ascorbic acid and inhibition, there are available a number of observations of the inhibitions produced by 10-min. treatments with different amounts of ascorbic acid. These observations, which were made at different times on three different enzyme preparations, serve to illustrate the general form of the relation (Fig. 4). (In all these cases 2 ml. of enzyme were pretreated with 1 ml. of solution containing the indicated amounts of ascorbic acid.)

The degree of inhibition rises rapidly with increasing amounts of ascorbic acid up to about 0.2 mg. (per 3 ml. enzyme-inhibitor mixture) but above this range of concentration the degree of inhibition rises only very slightly with increasing amounts of ascorbic acid.

\* Extrapolated values.

*Reversal of dienol inhibition by hydrogen cyanide, sulphydryl compounds  
and sodium hydrosulphite.*

In discussing the progress curves of maltose production (on which activity values are based) attention has already been drawn to the data of Table VI in which is shown the re-activation of the enzyme by cysteine after inhibition by the three dienol compounds.

It will be seen that the control enzyme is not appreciably influenced by treatment with cysteine (Digests 1 and 2). After treatment with ascorbic acid, reductone and dihydroxymaleic acid the activity was reduced to 23, 17 and 61.5 % respectively of the control value (Digests 3, 5 and 7) and after the 5-min. cysteine treatment these values were increased to 88.5, 88.5 and 103 % of the control (Digests 4, 6 and 8). There is thus a nearly complete removal of the inhibition by cysteine in all cases.

Other reagents effective in reversing the inhibition are hydrogen cyanide, sodium hydrosulphite, thiosalicylic and thioacetic acids. With the  $\beta$ -amylase preparations used in this investigation<sup>1</sup> none of these substances affected the activity of the non-inhibited enzyme to an appreciable extent except after prolonged storage at 0° when small activations by cysteine were observed, the greatest activation of this type being a 16 % increase in activity after pretreatment of 2 ml. enzyme for 20 min. with 4 mg. cysteine. In general pretreatment of the control enzyme with these reducing compounds resulted in barely significant inhibitions (of the order of 1 to 5 %). It may therefore be stated with assurance that the great increases in activity observed after treating the dienol-inhibited enzyme with these compounds are due to a reversal of the dienol inhibition.

In Table VI are given the results of three typical experiments illustrating the reversal of various dienol inhibitions by the group of activators mentioned above.

Table VI.

Exp.	Inhibition by 1 ml. containing	Reactivation by	I.V.	Relative activity
A	Control	—	0.322	100
	"	2 ml. 0.1 N HCN—5 min.	0.318	99

\* D.H.M. = dihydroxymaleic acid.

<sup>1</sup> In an investigation briefly reported earlier [Hanes and Barker, 1931] cyanide activations of certain  $\beta$ -amylase preparations from barley were observed.

Exp. A shows complete reversal of a 58% inhibition with dihydroxymaleic acid by cysteine and hydrosulphite treatments and a considerable reactivation by cyanide. The activity of the non-inhibited control was not influenced by cyanide pretreatment. We have included also with this experiment an observation which shows that maleic acid (neutralised to  $p_{\text{H}}$  6.4 as usual with reagents used in pretreatment) does not influence the activity of the enzyme.

In Exp. B are shown the effects of a variety of reactivation treatments (using cyanide and three different sulphydryl compounds) after an almost complete inhibition by ascorbic acid, and in Exp. C are shown reactivations after reductone inhibition. The control enzymes in these cases showed respectively a slight activation with cysteine and a slight inhibition with sodium hydrosulphite.

It is felt that the examples given in Tables V and VI are sufficient to establish the fact that the inhibition of  $\beta$ -malt-amylase by the three dienol compounds can be reversed completely or nearly completely by treatment with cyanide, hydrosulphite and various sulphydryl compounds. On the basis of numerous additional data now at hand it may be said that the concentrations of the different activators used in the above experiments are sufficiently great to induce maximum rates of reactivation, although in some of the experiments the duration of treatment was not long enough to allow the maximum reactivation to occur. A fuller discussion of the time relations of the reactivation and the relationship between the activity of the enzyme and the concentrations of dienol and activator is, however, beyond the scope of the data now available.

*The effects of other factors on the inhibition by ascorbic acid.*

(a) *The effects of added iron and copper.* Papain although inhibited by ascorbic acid alone is activated by treatment with ascorbic acid *plus* ferrous sulphate according to the observations of Maschmann and Helmert [1934]. In view of this effect,  $\beta$ -malt-amylase was subjected to similar treatment. It was found that the addition of ferrous sulphate with ascorbic acid resulted in slightly increased inhibition. Pretreatment of  $\beta$ -amylase with ferrous sulphate alone causes considerable inactivation; thus a 3-min. pretreatment with  $0.9 \times 10^{-5}$  M ferrous sulphate produced an 8% inhibition. With the higher concentrations such as were applied to papain by Maschmann and Helmert considerably greater inhibition results. We give an example in which the concentrations of iron and ascorbic acid are the same as those reported to activate papain. 2 ml. portions of enzyme were pretreated 10.5 min. with (a) 1 ml. ferrous sulphate ( $\equiv 3.15$  mg.  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ), (b) 1 ml. ascorbic acid ( $\equiv 0.2$  mg.), (c) ferrous sulphate *plus* ascorbic acid. The observed inhibitions were 63, 86 and 89% respectively. It can be concluded that added ferrous iron does not have the effect of converting the inhibitory effect of ascorbic acid into an activation in the case of  $\beta$ -amylase.

The addition of traces of copper sulphate in concentrations so low as to produce only slight inhibition when used alone were found greatly to increase the inhibition by ascorbic acid and reductone. It was found moreover that such inhibition in the presence of copper was only slightly reversible by subsequent treatment with hydrogen cyanide. Examples of this effect are shown in Table VII.

We are here reminded of the observations of Maschmann and Helmert on papain and Euler *et al.* [1934] on liver cathepsin that the addition of traces of cupric salts with ascorbic acid causes inhibition.

Table VII.

## A. Effect of addition of traces of copper sulphate with ascorbic acid.

	I.V.	Relative activity
(1) Control	0.376	100
(2) Control + 20 $\gamma$ CuSO <sub>4</sub> —5 min.	0.340	90.5
(3) Enzyme + 0.1 mg. ascorbic acid—5 min.	0.095	25
(4) As (3) followed by 2 ml. 0.1 <i>N</i> HCN—8 min.	0.352	93.5
(5) Enzyme + 0.1 mg. ascorbic acid + 20 $\gamma$ CuSO <sub>4</sub> —5 min.	0.005	1.3
(6) As (5) followed by 2 ml. 0.1 <i>N</i> HCN—8 min.	0.155	41

## B. Effect of addition of traces of copper sulphate with reductone.

(1) Control	0.310	100
(2) Enzyme + 0.1 mg. reductone—10 min.	0.044	14
(3) As (2) followed by 2 ml. 0.1 <i>N</i> HCN—6 min.	0.295	95
(4) Enzyme + 0.1 mg. reductone + 2 $\gamma$ CuSO <sub>4</sub> —10 min.	0	0
(5) As (4) followed by 2 ml. 0.1 <i>N</i> HCN—6 min.	0.130	42

(b) *The presence of acetate buffer.* The addition of the acetate buffer, which was used in maintaining the acidity of the starch digests, to the enzyme during pretreatment with ascorbic acid was found to increase the inhibition. For example, the addition of 0.01 *M* acetate of  $p_H$  4.7 during a 10-min. pretreatment with 0.05 mg. ascorbic acid increased the inhibition from 53 to 86%. Whether this effect is attributable to the increased acidity or to the presence of heavy metal impurities in the buffer has not been determined. It is mentioned merely as offering an explanation, at least in part, of the falling reaction rates observed in digests with inhibited enzyme (p. 2590 above).

(c) *Exclusion of oxygen during pretreatment.* We mention finally an experiment in which the enzyme was pretreated with ascorbic acid in the absence of oxygen. Use was made of a small glass vessel with two limbs in which were placed separately 2 ml. enzyme and 1 ml. of ascorbic acid containing 0.2 mg. The vessel was evacuated by means of an oil pump so as to induce gentle boiling of the solutions at room temperature. This was continued for 5 min., the vessel

Fig. 5. Progress curves of maltose production with untreated enzyme and enzyme pretreated 15 min. with 0.2 mg. ascorbic acid (a) in air, (b) in absence of oxygen.

being shaken continuously. The two solutions were then mixed, tipping from one limb to the other several times, and were left 15 min. in the evacuated vessel. The vessel was then opened and the inhibitor-enzyme mixture was added

to the digest, the vessel being rinsed out with the digest fluid. A second portion of enzyme was then pretreated in the same vessel without evacuation. The progress curves for these enzymes, together with that of the untreated control, are shown in Fig. 5.

It will be seen that the exclusion of oxygen during pretreatment had no significant effect upon the development of the inhibition, the initial velocities of maltose production being the same and indicating an inhibition of approximately 80% of the untreated control. (The more rapid fall in the reaction rate in the progress curve with enzyme pretreated anaerobically is possibly not significant since as we have mentioned earlier considerable variability in this effect is encountered.)

#### DISCUSSION.

The experimental results demonstrate that  $\beta$ -malt-amyase is inhibited by the reduced forms of *l*-ascorbic acid, reductone and dihydroxymaleic acid. These compounds, whose formulae are set out below, have in common the possession of the strongly reducing dienol grouping but are in other respects widely dissimilar.

That the inhibition of the enzyme by the three compounds is of the same nature is strongly indicated by certain peculiarities of the effect in each case. The unusual features of this particular type of inhibition are that it is reversed on the one hand by oxidative treatments which destroy the dienol grouping, and on the other hand by the addition of a variety of reducing substances (of widely different reducing power). We are thus led to the conclusion that the inhibition is due to the presence of the dienol grouping, and moreover that the inhibitory action of this grouping is not due merely to its reducing properties but is more specific in nature since the effect is reversed by the addition of other reducing substances which have no appreciable effect on the activity of the non-inhibited enzyme.

It is worthy of mention that dihydroxymaleic acid produces a considerably smaller inhibition than ascorbic acid or reductone in the same molar concentration, the latter two compounds inhibiting to approximately the same extent (*cf.* p. 2592). This fact suggests that the particularly reactive "endiol" configuration which occurs in ascorbic acid and reductone possesses a greater inhibitory power than the dienol grouping as it occurs in dihydroxymaleic acid. Further investigation to test this suggestion is desirable.

The most unusual feature of this inhibition by dienol compounds is its reversibility either by oxidative treatments or by the addition of a variety of reducing substances. Thus we have presented data illustrating reactivations on the one hand by molecular oxygen, methylene blue and ferricyanide, and on the other by sodium hydrosulphite, sulphhydryl compounds and cyanide.

The mechanism of the reversal of inhibition by oxidative treatments would appear to be relatively simple and would seem to be the result of the destruction of the inhibiting group by oxidation. (It seems probable from the results with ferrieyanide that the oxidation of ascorbic acid to the reversibly oxidised state destroys the inhibitory action although this cannot be held to be definitely established, cf. p. 2596.)

The mechanism underlying the reversal of the dienol inhibition by cyanide, hydrosulphite and sulphydryl compounds remains obscure and our present data are inadequate for its elucidation. The different cases in which activations of other hydrolytic enzymes have been reported by members of this same group of substances would appear to involve effects of two distinct types: (1) the removal of heavy metal inhibitors (in which case the activators are effective by virtue of their ability to form complexes with the inhibiting metal ion); (2) the reversal of inactivations which are the result of reversible oxidation of some essential part of the enzyme complex [e.g. Hellerman and Perkins, 1934]. It is evident that serious difficulties are encountered in attempting explanations of the inhibition of  $\beta$ -amylase by dienols and the reactivation by the group of activators mentioned, along either of these recognised lines. It is hoped that additional data bearing on this problem will be available shortly.

Although the mechanism remains obscure, the effect appears of considerable interest as representing a type of reaction which may be of importance in the physiology of ascorbic acid. We refer in particular to the opposing actions of sulphydryl compounds on the one hand and of ascorbic acid on the other in their effects on this enzyme. In this connection the observation of Birch and Dann [1933] that ascorbic acid and glutathione occur commonly together in the tissues of the animal body is suggestive. While these authors regard the parallelism in distribution as evidence that the two substances are components of a single oxidation system, our present effect suggests the possibility that they may function as the opposing elements of an enzyme regulatory mechanism.

It may be stated finally that there remains the possibility that effects of a similar nature to those described for  $\beta$ -malt-amylase may occur with other enzyme systems. In particular, attention is called to the cases of papain and urease which are inhibited by ascorbic acid according to the reports of Maschmann and Helmert [1934] and Edlbacher and Leuthardt [1933] respectively. (It is to be noted that papain, unlike  $\beta$ -amylase, is activated by ascorbic acid *plus* iron.) Both papain and urease are known to be activated by cyanide, hydrosulphite and sulphydryl compounds after certain "heavy metal" and "oxidative" inactivations [Hellerman and Perkins, 1934; Hellerman *et al.*, 1933] and it would be of great interest to know whether the same group of substances is effective in reversing the reported inhibitions of these enzymes by ascorbic acid, as is the case with  $\beta$ -malt-amylase.

#### SUMMARY.

1. Treatment of  $\beta$ -malt-amylase with reduced ascorbic acid results in inhibition. The inhibition is not "instantaneous" but requires a measurable time for maximum development. During prolonged pretreatment of the enzyme with ascorbic acid a slow regeneration of activity occurs.

2. Reductone and dihydroxymaleic acid likewise inhibit the enzyme. The inhibitions by equivalent concentrations of ascorbic acid and reductone are of the same order, which is considerably greater than that by dihydroxymaleic acid.

3. During pretreatment of the enzyme with reductone and dihydroxymaleic acid a relatively rapid regeneration of activity occurs. This reversal of the inhibition is shown to be related to the destruction of the dienol grouping by oxidation.

4. It is shown that the presence of the enzyme extract protects ascorbic acid against oxidation whereas it accelerates the destruction of reductone and dihydroxymaleic acid.

5. Preliminary aerobic oxidation of ascorbic acid and reductone destroys their inhibitory power.

6. The addition of methylene blue and ferricyanide (which exert only very slight inhibitions on the enzyme) reverses the inhibition by ascorbic acid.

7. The addition of hydrogen cyanide, sodium hydrosulphite, cysteine, thio-salicylic acid and thiolacetic acid reverses the inhibition by the three dienol compounds.

8. The addition of ferrous sulphate has little effect upon the degree of inhibition by ascorbic acid but traces of copper cause increased inhibition.

9. Exclusion of oxygen does not significantly affect the development of the inhibition.

I wish to express my indebtedness to Mr James Alexander for invaluable technical assistance.

# CCCX. THERMOCHEMISTRY OF THE OXYGEN-HAEMOGLOBIN REACTION.

## I. DIRECT MEASUREMENTS OF THE HEAT OF REACTION UNDER VARIOUS CONDITIONS.

BY FRANCIS JOHN WORSLEY ROUGHTON.

*From the Physiological Laboratory, Cambridge.*

*(Received October 1st, 1935.)*

BROWN AND HILL [1923] have published the last direct measurements (known to the writer) on the heat of reaction of oxygen with haemoglobin. Since then, the subject has lain practically dormant, nor has much attention been given to the allied problem of calculating the heat of this reaction indirectly from the effect of temperature upon the oxyhaemoglobin dissociation curve. Great advance has, however, been made in the elucidation of other physico-chemical properties of haemoglobin; notably in regard to the molecular weight [Adair, 1925, 1, 2; Svedberg and Fahraeus, 1926], and in regard to the titration curves and buffer power of oxyhaemoglobin and reduced haemoglobin [Van Slyke *et al.*, 1921 and onwards—summarised by Peters and Van Slyke, 1931]. This new knowledge has much bearing upon the thermochemistry of the oxygen-haemoglobin reaction, and indeed points to certain gaps and doubtful assumptions in the previous work.

The objects of the present series of papers were as follows:

(a) To test by direct calorimetry whether the heat,  $Q$ , per g. mol. of  $O_2$  (or CO) combining with haemoglobin, when this amount of  $O_2$  (or CO) is employed in saturating the haemoglobin partially, is independent of the percentage saturation attained.

Direct tests of this kind do not seem to have been made and perhaps would hardly be worth making if the reaction between oxygen and haemoglobin were a single, straightforward reaction, *i.e.*

Since, however, the molecular weight of haemoglobin is 68,000, one molecule of reduced haemoglobin combines reversibly with four molecules of oxygen, which, as suggested by Adair [1925, 1, 2], it probably does in four intermediate stages, *viz.*:

$Q_1, Q_2, Q_3, Q_4$  may not necessarily be the same: if they are different the overall heat,  $Q$ , might not be independent of the percentage saturation. If the latter were indeed found experimentally to be the case, it would be concrete evidence in favour of the intermediate compound hypothesis: a converse finding would not, however, disprove the existence of the intermediate compounds. This point will be discussed more fully in a later paper.

(b) To test whether the heat of reaction of oxygen with haemoglobin is affected by (i) laking of the corpuscles, (ii) purification of the haemoglobin.

No definite information on either of these points seems to be available in the previous literature of the subject.

(c) To investigate further the relation between the heat of the reaction, the  $p_{\text{H}}$  and the buffer content of the solution.

Brown and Hill [1923] were the first to point out that the heat evolved when oxygen combines with haemoglobin is really the sum of the heats of three separate processes.

(i) The primary reaction between oxygen and haemoglobin—the heat per g. mol. O<sub>2</sub> combining being of the order of 11,000 to 14,000 calories.

(ii) Oxyhaemoglobin being a stronger acid than reduced haemoglobin, oxygenation of the latter leads to the splitting off of H ions, probably from a special NH<sub>3</sub><sup>+</sup> group in the neighbourhood of the haematin nucleus (which group may, following Van Slyke, be referred to as the oxy-labile group). The heat absorbed per oxy-labile H ion so liberated is considered to be about 10,000 calories.

(iii) The liberated oxy-labile H ions do not remain free in solution but are removed by the buffer substances present therein. The accompanying heat effect obviously depends on the respective concentrations and heats of ionisation of the various buffer systems.

On this basis it is clear that the “overall” heat depends not only on the haemoglobin but also on the nature and concentrations of all other buffers in the system. Under certain conditions indeed (*v. infra*) the overall heat may be expected to differ considerably from the heat of the primary process (i).

Brown and Hill's detailed working out of this conception requires revision in the light of our more recent knowledge: further data over a wider range of  $p_{\text{H}}$  are also desirable.

(d) Hartridge and Roughton [1923, 1, 2; 1925], with the aid of their rapid velocity technique, have shown that the combination of oxygen and haemoglobin is, under normal conditions, complete in about 1/100 sec., if the difference in optical properties of oxy- and reduced haemoglobin is used as the criterion of the chemical change. It would be of interest to know whether the large heat effects associated with the reaction also occur at the same speed: a discrepancy therefrom would be of much significance for it would have to be attributed to the occurrence of some other reaction besides the primary combination of oxygen with haemoglobin, which would of course entail a revision of our views as to the mechanism of the whole process.

This question cannot, like the others, be tackled by the ordinary methods of slow calorimetry for in these the temperature changes to be measured are spread out over a period of 10 min. or more, owing to the slowness of diffusion of oxygen in solution and the slowness of heat conduction within the calorimeter: it requires instead the application of the rapid method developed by Roughton [1930, 1, 2].

(e) To compare in the case of purified haemoglobin solutions the heat of reaction of oxygen with haemoglobin, as measured directly, with that calculated indirectly from the effect of temperature on the oxyhaemoglobin dissociation curve by means of the van't Hoff isochore. This has not been attempted since the pioneer work of Barcroft and Hill [1909] in which, however, remarkably high values for the heat of reaction were recorded. Both in the latter work and in that of Brown and Hill [1923] on whole blood the oxygen contents of the solutions were estimated by the Barcroft-Haldane blood-gas methods, which are now known to give results which are often, though not invariably, too low [*v. Abeloos et al.*, 1928].

Fairly complete sets of experiments on questions (a) and (b) are given in this paper, together with experiments and detailed theory in regard to question (c). Question (d) is dealt with in the succeeding paper by Bateman and Roughton whilst in a future paper it is hoped to give a comparison of the heat measured directly for purified haemoglobin solutions, both at  $p_H$  6.8 and at *ca.* 9.5, with that calculated indirectly from the effect of temperature on the oxyhaemoglobin dissociation curve together with some theoretical considerations arising therefrom.

The present paper is confined on the experimental side to direct measurements of the heat of reaction by the classical method of slow calorimetry, the technique for which will first be described: then follow the experimental results, together with some theoretical discussion arising out of the effect of  $p_H$  on the directly measured heats.

Unless otherwise stated defibrinated ox blood, from the slaughter house, was used for the experiments given in these papers, whether on whole blood or on purified haemoglobin. All experiments were done at 19–20°; oxygen contents were estimated, when required, in the Van Slyke-Neill constant volume apparatus.

The figures given in this paper refer throughout to the heat of the reaction

The heat of solution of  $\text{O}_2$ , *viz.* 2800 calories at 17°, must be subtracted from them, if it is desired to obtain the heat of the reaction

#### EXPERIMENTAL METHODS.

In general outline the method used was as follows.

Reduced blood (or haemoglobin solution) was shaken with oxygen or carbon monoxide in one thermos flask, and the temperature difference between this and a second thermos flask, containing the same amount of fluid but with no chemical reaction occurring therein, was measured thermo-electrically. The technique embodied certain features of the differential method of Hill [1911], and also of the respective methods of Brown and Hill [1923] and of Roughton [1930, 1, 2]. The details of the apparatus were largely governed by what parts were at hand or readily available.

(a) *The calorimeters and their contents* (*v.* Fig. 1). These consisted of two thermos flasks  $Th$ ,  $Th'$ , capacity 400 ml. each, and selected so as to have as nearly the same thermal conductivity as possible. A narrow-mouthed variety of flask (1 in. diameter mouth) was used, so as to cut down heat exchange through the mouth. The flasks were each fitted with rubber corks, through which six holes were drilled. Through two of these holes passed thick-walled glass capillary tubes (internal bore 1 mm.) which were used for filling and emptying the flasks with liquid and/or gas. (These tubes ended flush with the inside surface of the rubber cork.) Two other of the holes were used for the glass U-tubes  $U$ ,  $U'$ , through which could be circulated a stream of constant-temperature water, so that the internal temperatures of the flasks could by this means be readily adjusted so as to be as nearly as possible equal to one another and to that of their outside environment. The fifth hole conveyed the connections of the electric heater, which was used to calibrate the flasks, whilst the sixth hole conveyed a glass tube  $T$ ,  $T'$  reaching to the bottom of the flask and closed at the lower end. These tubes were filled with water, the thermo-junctions were then placed inside

them and the top ends sealed so as to prevent evaporation of the water. Further details as to the electric heating and the thermocouples were as follows:

(b) *The electric heaters.* These were made of fine constantan wire and each had a resistance of about 110 ohms. The heating current was furnished by six 2-volt accumulators in series, and was measured by a milliammeter. The heat supplied = (current)<sup>2</sup> × (resistance) × (time).

The current was usually 80–100 milliamps, the time 100 sec. and the heat supplied 10–12 calories.

Fig. 1. The calorimeter. Arrangement and connections of twin thermos flasks in box attached to shaker. In order to make the interior construction of the two flasks clear, the spiral tubing which actually encloses the flasks completely is shown as cut away except at the bottom of the flasks.

(c) *The thermocouples.* These were made of copper and constantan and were bent into the shape of a U, one limb of which (consisting of the warm junctions) was pushed into  $T$ , whilst the other was pushed into  $T'$ . From the centre of the U heavy leads connected to the electric recording system. Sufficient sensitivity was attained with only two or four thermojunctions. The electrical resistance of the thermocouples was from 10 to 20 ohms, and the thermo-electric current was measured by direct deflection of the galvanometer, not potentiometrically, since the E.M.F.'s developed were so small.

(d) *The heat insulation of the thermos flasks and constancy of temperature of external environment.* Each of the thermos flasks was completely encased from top to bottom by a close-fitting spiral of lead tubing, which was connected with a supply of constant-temperature circulating water (constant to  $\pm 0.05^\circ$ ). The two flasks and their encasements were then buried in cotton-wool (1 to 2 in. thick) in a metal box, which was attached in a horizontal position to a board hinged to a large shaking machine. The latter, when set into operation, tilted the flasks to and fro about 100 times per minute. This rate was usually enough to bring the fluids and gases into thermal and chemical equilibrium in about 15 min., without at the same time causing any serious temperature differences between them due to the mechanical heat of fluid friction. In an actual experiment, after the requisite solutions had been placed in the thermos flasks, the shaker was started, and the constant temperature water was circulated round the outside of the flasks and through the inner tubes  $U$ ,  $U'$ .

Usually after about 2 hours' circulation the interior and exterior of the thermos flasks were sufficiently near to each other in temperature for the actual experiment to be performed.

At this stage the inner circulation through  $U$  and  $U'$  was, by suitable manipulation of clips on the rubber connections, cut off. From this point onwards the circulation only passed through the coils on the outside of the two thermos flasks.

(e) *Preparation of the reduced blood (or haemoglobin) and loading thereof into the thermos flasks.* About 400 ml. of blood or haemoglobin were reduced in a 2-litre bottle by continued boiling and shaking *in vacuo*, according mainly to the directions of Forbes and Roughton [1931], save that small doses of purified nitrogen were often introduced into the bottle after each evacuation so as to make the foam subside more readily. 20 min. were usually enough for complete reduction, but the procedure was always continued 5 to 10 min. more, to make sure that no oxygen was left in the blood. The bottle was then filled with oxygen-free nitrogen (prepared fresh for each experiment by keeping commercial nitrogen in a 10-litre bottle over a solution containing 20% sodium hydrosulphite and 1% sodium  $\beta$ -anthraquinonesulphonate) and immersed upside down for 1-2 hours in a water thermostat of the same temperature as the circulating water, so as to be at about the right temperature before being put into the thermos flasks.

A known volume, usually 195 ml. of reduced blood (or haemoglobin solution) was then transferred without contact with oxygen into  $Th$  and the same volume, though not necessarily of the same fluid, transferred into  $Th'$ .  $Th$  and  $Th'$  were finally left full of oxygen-free nitrogen at atmospheric pressure.

(f) *Further procedure during an actual experiment.* During the temperature equilibration in (e), the shaker was continually in motion. After about 1 hour the "inner" circulation was cut off, and galvanometer readings of the temperature difference between  $Th$  and  $Th'$  were taken every minute. If the temperature difference was small enough (i.e.  $< 0.1^\circ$ ) and if the rate of drift of the temperature difference was also sufficiently slight (i.e. of the order of  $0.0001^\circ$  per min. in good experiments) the experiment could be continued. In certain cases the drift was much faster and could not be cut down. In these, and in other cases, where necessary, the drifts were allowed for by means of the usual "cooling curve" procedure.

The first thermos was then calibrated by electric heating for 50 to 100 sec., the shaker working the whole time. Galvanometer readings were taken at minute intervals for 5 min. after the heating. By this time conditions were steady again. The second thermos was then calibrated in the same way.

From 10 to 50 ml. of gas ( $O_2$  or  $CO$ ) were then measured into a burette with mercury reservoir, and forced by the latter into one of the thermos flasks. The gas was as a rule either dry or saturated with water vapour. Corrections were applied for the heat effects due (a) to the compression of the gas into the flask, (b) to the water vapour in the gas but not for (c) the difference in the temperature between the gas and the inside of the flask, since correction for this was found to be negligible. These corrections, as given by theoretical calculation, were only of the order of 5-10% of the observed heats. In control experiments, in which the thermos flasks held 1% boric acid solution instead of blood, and in which similar volumes of air were forced in as above, the heat effects found agreed closely enough with those calculated on the same basis as the corrections just described. Brown and Hill [1923] avoided these corrections by a special

procedure, and their final accuracy was, on this account, probably better. The present technique, however, has the advantage of enabling the heat liberated when successive amounts of CO (and in some cases of  $O_2$ ) are introduced into the same flask to be simply measured.

The introduction of the gas took about 2 min., during which time the shaker was still. The shaker was then started up again and galvanometer readings taken every minute for about 20 min. The chemical process, as a rule, was finished in 10 min., and the remaining 10-min. period was used for finding out the rate of drift again.

The second thermos flask was then treated in the same way. If necessary the first thermos was again treated with gas, and then the second and so on—the two thermos flasks always being treated alternately so as to keep the temperature difference between the two flasks small.

At the end of the experiment the flasks were tilted vertically and, if required, blood was run out from each under paraffin oil for analysis of its gas content in the Van Slyke-Neill apparatus. Since the blood was initially reduced, the  $O_2$  or CO content so found =  $O_2$  or CO uptake during the experiments apart from a small amount in physical solution, which could be allowed for.

In some cases the gas uptake by the blood was obtained indirectly from the amount of gas introduced into the thermos flask, the volumes of the gas and liquid phases therein and the oxyhaemoglobin dissociation curve. In a few experiments the final  $p_H$  was measured by means of the glass electrode.

The two flasks were then thoroughly washed out with water or dilute ammonia, and were finally left completely full with 1% boric acid solution, so as to inhibit bacterial growths. The boric acid was not removed until the beginning of the next experiment.

The thermocouple was connected in series with a Zernicke Zb galvanometer, readings of which were taken on a scale at 4 metres distance. The galvanometer was permanently shunted with a manganin resistance of about 50 ohms, so as to give critical damping of the coil when a high resistance was in series with it. The usual resistance in series was very low, i.e. 10–50 ohms, so that the coil was often over-damped, but this did not matter in the present work.

The sensitivity was from 1.5 to 6.0 mm. deflection per 0.001°. A double potentiometer arrangement arranged so as to be as free as possible from parasitic E.M.F.'s, enabled the voltage sensitivity of the galvanometer to be checked with small micro-voltages, and also served partially to compensate the thermo-E.M.F.'s if the latter happened to be unduly large in any special case.

(g) *Purity of gases used.* The carbon monoxide was prepared from sodium formate and sulphuric acid and was stored under a slight positive pressure over alkaline sodium hydrosulphite. It was therefore free of  $O_2$  and  $CO_2$ , but usually contained 1–4% impurity which was presumably mainly nitrogen.

The oxygen was drawn from an ordinary commercial cylinder and was usually 99% pure.

(h) *Accuracy of the method.* When whole blood, or haemoglobin solution of equivalent oxygen capacity, is saturated with oxygen, there is a rise of temperature of 0.06–0.10°. In good experiments the temperature difference between the flasks remained constant to within 0.001° after each equilibration, or failing that showed only a small and regular drift, the correction for which did not amount to more than 0.003–0.004°; the method was then found to be reliable on the average to  $\pm 0.002^\circ$  which would be equivalent to an error of  $\pm ca.$  300 calories in the heat of combination of 1 g. mol. of oxygen with haemoglobin if the concentration of the latter is as in whole blood.

In poor experiments, in which the drifts were greater or more irregular, the error might be 2 or 3 times larger. Amongst the causes responsible for such may be mentioned:

- (i) Unequal dimensions and/or thermal conductivity of the two flasks.
- (ii) Imperfect balancing of the frictional heat due to shaking in the two flasks.
- (iii) The occurrence of slow secondary processes.

The flasks were therefore carefully chosen so as to be equal<sup>1</sup> in size and thermal conductivity (to within 2–3 %), and where possible the same solution was placed in each: in some of the experiments on purified haemoglobin, this, unfortunately could not be done, owing to shortage of material. The experiments on purified haemoglobin were, in fact, less satisfactory than those on whole blood, especially at  $p_{11}$  6.8: this was in part due to the reason just given, but it may also have been in part due to the readier denaturation of haemoglobin when pure and possibly to other causes as well.

#### EXPERIMENTAL RESULTS.

##### (a) *Relation between heat liberated and percentage saturation.*

Three or more instalments of gas ( $O_2$  or CO) were forced into one or both flasks, and the heat developed after equilibration with each in turn was measured. The volume of gas so introduced was such as to saturate the Hb to about 25 %. In this way several points were obtained over the range of 25–90 % saturation.

Unfortunately, however, the heat developed is in each case small, and the experimental error of the method therefore causes a correspondingly great uncertainty in the result. Thus *e.g.* if the temperature rise for 100 % saturation were  $0.1^\circ$  (a normal figure) then the temperature rise for 25 % saturation would be  $0.025^\circ$ , if  $Q$  is independent of the % saturation: so an experimental error of  $0.001^\circ$  would cause an uncertainty of 4 % in the answer, whilst an error as large as  $0.005^\circ$  would give a 20 % uncertainty—a figure much too big unless very many experiments were done. Since whole blood generally gave more precise results than purified haemoglobin, the seven experiments on this question were all done with whole blood. Of these two were done with carbon monoxide and five with oxygen.

(1) *Experiments with CO.* The first experiment on this subject with CO gave most satisfactory results. Pig's blood, treated with 1 % boric acid was used in each thermos flask.

In Fig. 2a, the volume of CO added is plotted against the heat change, expressed in cm. of galvanometer deflection. Owing to the very high affinity of the Hb for CO, the amount of residual CO left in the gas phase of the flask after each equilibration was negligible, and the CO uptake is therefore simply equal to the volume of CO introduced into the flask. No corrections were made for the heat effects due to the introduction of CO into the flask, since these being proportional to the volume of CO introduced, would not affect a linear relationship between heat observed and volume of CO introduced. The temperature after each equilibration remained steady to within  $0.0002^\circ$  for 5 min., so no corrections for drift were needed.

<sup>1</sup> In the middle of the research one of the flasks was broken and had to be replaced quickly with another flask which was not a good match of the sound one. Later on, this was rectified.

For the three points shown in Fig. 2*a*, the actual values for the heat evolved were in  $\frac{\text{cm. deflection}}{\text{ml. CO added}}$ :

0.556, 0.525 and 0.558 respectively: Mean = 0.545.

The largest discrepancy from the mean is thus only  $100 \times \frac{0.545 - 0.525}{0.545} \% = 3.7 \%$ , and is thus well within the experimental error.

Fig. 2*a*.

Fig. 2*b*.

Fig. 2. Relation between volume of carbon monoxide added and heat evolved, when blood and gas phase are equilibrated.

In the second experiment (Fig. 2*b*) calf's blood containing 1% boric acid + phosphate buffer.  $M/5$ , final  $p_H$  about 6.8 was used. The blood in one flask was laked by freezing and thawing and in the other unlaked. This experiment, owing to drifts, was less satisfactory and the results were rather irregular, but in general confirmed the conclusion obtained in the original experiment.

(2) *Experiments with oxygen.* Owing to the smaller affinity of haemoglobin for oxygen (than for carbon monoxide), the oxygen uptake must be somewhat less than the volume of oxygen introduced into the flask. This makes it desirable to withdraw a sample of blood after each equilibration and analyse its oxygen content in the Van Slyke-Neill apparatus. Unfortunately a single experimenter could not do this, as well as the heat experiment, within a period of 1 day—a necessary time-limit if disturbance due to changes in the blood are to be certainly avoided.

The difficulty was got over in the following way. In the two experiments shown in Fig. 3, the analysis of the O<sub>2</sub> content of the blood in the flasks at the end of the experiment showed that the residual O<sub>2</sub> in the gas phase was about 10% of the total volume put in. In these cases the blood was more than 80% saturated, i.e. its condition was represented by a point on the flat part of the oxyhaemoglobin dissociation curve at the top. Now on the steep part of the curve below 80% saturation the residual O<sub>2</sub> in the gas phase must be less than 10% of the O<sub>2</sub> taken up, and, furthermore, inspection of the dissociation curve shows that over the range 25–80% O<sub>2</sub>Hb the relation between O<sub>2</sub> pressure and % O<sub>2</sub>Hb does not differ from a straight line by more than 15%. If the experimental relation between volume of O<sub>2</sub> introduced and heat produced be linear, then it follows that the correction for the residual O<sub>2</sub> in the gas phase would not cause a distortion of more than 15% of 10%, i.e. 1.5% from a straight line, if true O<sub>2</sub> uptake were plotted against heat over the range 25–80% O<sub>2</sub>Hb. Since

such an error of 1.5% is small compared with that of the method as applied to this problem, *viz.* 5%, it was considered that the plotting of vol. O<sub>2</sub> introduced against heat developed gave a satisfactory test over the range of 25–80% O<sub>2</sub>Hb.

The results of two experiments on two different specimens of ox-blood containing 1% boric acid + *M*/10 phosphate buffer  $p_H$  *ca.* 7.0 are given in Fig. 3*a* and *b*.

Fig. 3*a*.Fig. 3*b*.

Fig. 3. Relation between volume of oxygen added and heat evolved when blood and gas phase are equilibrated.

In Fig. 3*a*, the first four points lie on a straight line to within 3% whilst the last two points lie above the line owing to the fact that the blood was nearly fully saturated, so that a relatively larger correction for residual O<sub>2</sub> in the gas phase would be necessary. In this case the blood was laked by addition of 1% saponin.

In Fig. 3*b* one thermos flask contained the above blood mixture unlaked whilst the second contained similar blood mixture, but laked by freezing and thawing. These points all fell on a straight line to within 6%.

In a third experiment, not shown, on ox-blood + 1% boric acid  $p_H$  7.5 (about) two points were obtained. For these the divergence from a straight line was 3%. Two other experiments also gave confirmatory results.

The general conclusion is therefore that for oxygen, over the range investigated, *i.e.* 25–80% saturation, and for carbon monoxide over the range investigated, *i.e.* 25–90%, the heat developed is within experimental error proportional to the gas uptake in the case of whole blood, whether laked or unlaked. *Q* appears to be independent of the percentage saturation within this range: these experiments therefore fail to yield any positive evidence for the existence of the intermediate reactions, though they do not, of course, disprove the possibility of their occurrence.

#### (b) *Effect of purification and of laking.*

(1) *Purification.* The heat of combination of oxygen with haemoglobin in laked blood and in purified solution has been compared, both at  $p_H$  6.8 and at  $p_H$  *ca.* 9.5. The haemoglobin was purified by Adair's method [Adair *et al.*, 1921] in each case. In the experiments at  $p_H$  6.8 the purified haemoglobin was dissolved in *M*/15 phosphate buffer, whereas the laked blood contained *M*/10 phosphate buffer: had the importance of the concentration of the foreign buffer been appreciated at the time the experiments were done, the same concentration would have been used in the two cases. The discrepancy was, however, allowed for well enough by adding on a figure of 600 calories to the values found in the case of the *M*/10 phosphate solutions: this figure of 600 calories was

arrived at by the method of calculation described in the theoretical section below (*q.v.*). In the comparison at alkaline  $p_{\text{H}}$ , both the laked blood and the haemoglobin solution were brought to  $p_{\text{H}}$  *ca.* 9.5 by adding an appropriate amount of NaOH: in this  $p_{\text{H}}$  range the heat of reaction is theoretically independent both of  $p_{\text{H}}$  and of the presence of foreign buffers.

The results of these comparisons are shown in Table I.

Table I. *Comparison of heat of reaction of oxygen with purified haemoglobin and with laked blood.*

$p_{\text{H}}$	Pure Hb	Laked blood	Unlaked blood
6.8 (phosphate buffer)	9,000 $\pm$ 700	8,700	9300
6.8 " "	9,700	9,400	—
6.8 " "	9,000	8,800	—
<i>ca.</i> 9.5 (NaOH added)	14,250	13,400	—

The heats of the reaction of oxygen with purified haemoglobin are, on the average, 400 calories higher than with laked blood, but the difference can hardly be regarded as outside experimental error.

(2) *Laking*. That laked blood and unlaked blood have practically the same heat of reaction at  $p_{\text{H}}$  6.6–6.8 (phosphate buffer) is shown by Figs. 2*b*, 3*b* and by the first line of Table I. This  $p_{\text{H}}$  range was chosen, because there is practically no difference in the H ion concentration, or according to Maizels and Hampson [1927] in the phosphate concentration, between the interior of the red blood corpuscle and the surrounding fluid. In future experiments it would, however, for reasons given later, be better to compare the heat of reaction of oxygen with corpuscles suspended in isotonic NaCl, with the heat of reaction of the same suspension when laked.

(c) *Effect of  $p_{\text{H}}$  and foreign buffer content.*

Table II shows the heat of reaction of purified Hb (prepared from the blood of several different animals) with oxygen at  $p_{\text{H}}$  *ca.* 6.8 and  $p_{\text{H}}$  *ca.* 9.5. The values, calculated indirectly from the effect of temperature on the dissociation curve

Table II. *Heat of reaction of purified haemoglobin with oxygen at various  $p_{\text{H}}$  values.*

$p_{\text{H}}$ and buffer concentration	Directly measured heat	Heat calculated indirectly from effect of temperature on dissociation curve
<i>ca.</i> 6.8, <i>M</i> 15 phosphate	9,000 $\pm$ c. 700	9,450
<i>ca.</i> 6.8, <i>M</i> 15 phosphate	9,700 $\pm$ c. 700	9,450
<i>ca.</i> 6.8, <i>M</i> 15 phosphate	8,800	—
<i>ca.</i> 7.5 distilled water	12,000	—
9.9, <i>M</i> 10 borate	—	15,000
<i>ca.</i> 9.5 (by addition of NaOH to Hb in distilled water)	12,400	12,400
<i>ca.</i> 9.5 " " " "	14,250	14,200

of the same haemoglobin solutions (to be described in a later paper) are for convenience also inserted. It will be seen that:

(i) There is good agreement between the direct and the indirect heats.

(ii) The variation between different samples at the alkaline reaction is about three times greater than at  $p_{\text{H}}$  6.8.

(iii) The average heat at the alkaline reaction, *viz.* 13,300, is about 4300 calories greater than the heat at  $p_{\text{H}}$  6.8, *M* 15 phosphate buffer, *viz.* 9300 calories.

A number of experiments have also been done on unalaked blood treated with phosphate and borate buffers of various strengths. The results, which are not included in this paper, did not show as large an influence of the foreign buffer concentration as would be expected on the basis of the theory to be given in the next section. It is known however that the concentration of the foreign buffer in the fluid outside the red blood corpuscles may, at equilibrium, be much higher under certain circumstances than inside the corpuscles, and furthermore that equilibrium may be reached slowly. The foreign buffers may thus play a smaller rôle than if the haemoglobin solution were homogeneous. This makes the interpretation of experiments on unalaked blood obscure, unless there are no foreign buffers present at all in the blood: it is for this reason that any future experiments on the effect of laking are to be performed on corpuscles suspended in unbuffered NaCl solution.

THEORETICAL INTERPRETATION OF THE EFFECT OF  $p_H$  AND FOREIGN  
BUFFERS ON THE HEAT OF REACTION OF OXYGEN WITH HAEMOGLOBIN.

This problem has already been outlined under heading (c) (p. 2605). In the quantitative treatment now to be given it will be assumed that:

(a) The reduced haemoglobin is treated with enough oxygen to saturate it completely: this avoids complications from compounds intermediate between  $Hb_4$  and  $Hb_4O_8$ .

(b) Of the H ions which combine with haemoglobin on the alkaline side of the isoelectric point there is, per mol. of oxygen-combining capacity, only one (called the "oxy-labile" hydrogen ion) whose ionisation constant is increased by oxygenation and lowered by reduction of 1 g. equivalent of haemoglobin. The experimental results of Hastings *et al.* [1924] are in accord with this view, though they do not prove it conclusively: so also are Hartridge and Roughton's [1923, 2] observations on the rate of dissociation of oxyhaemoglobin at various  $p_H$  values. It is a reasonable theory from the chemical point of view and is the simplest way of accounting for several different kinds of experimental result. It has therefore been thought fit to adopt it in this paper.

*Symbols and data required.*

Let  $[Hb^-]$  = concentration in equivalents<sup>1</sup> of reduced haemoglobin, in which the "oxy-labile" hydrogen ion is split off.

$[Hb]$  = concentration of reduced haemoglobin, in which the "oxy-labile" hydrogen ion is still attached.

$[O_2Hb^-]$  = concentration of oxyhaemoglobin, in which the "oxy-labile" hydrogen ion is split off.

$[O_2Hb]$  = concentration of oxyhaemoglobin, in which the "oxy-labile" hydrogen ion is still attached.

$A$  = total concentration of foreign buffer per equivalent of total haemoglobin.

$[H^+]$  = hydrogen ion concentration of the solution in general.

$H$  = hydrogen ion concentration of the solution after oxygenation.

$H'$  = hydrogen ion concentration of the solution before oxygenation.

$K_O$  = oxy-labile ionisation constant of oxyhaemoglobin =  $\frac{[O_2Hb^-][H^+]}{[O_2Hb]}$ ,

whence

$$\frac{[O_2Hb^-]}{\text{Total } Hb} = \frac{K_O}{K_O + H^+}.$$

<sup>1</sup> 1 equivalent of haemoglobin = amount which combines with 1 g. mol. of oxygen, viz. 17,000 g.

For horse haemoglobin, in solutions of about the same total electrolyte concentration as in the cases calculated below,  $K_O$  is about  $10^{-6.57}$  at  $38^\circ$  according to Hastings *et al.* [1924]. The change of temperature from  $38$  to  $18^\circ$  is allowed for by the Van't Hoff isochore, assuming the heat of ionisation to be 9000 calories; this lowers the value of  $K_O$  from  $10^{-6.57}$  at  $38^\circ$  to  $10^{-7.0}$  at  $18^\circ$ .

In the cases calculated below at  $18^\circ$   $K_O$  is taken as  $10^{-7.0}$ , and  $p_{K_0} = 7$ .

$K_R$  = oxy-labile ionisation constant of reduced haemoglobin =  $\frac{[\text{Hb}^-][\text{H}^+]}{[\text{Hb}]}$ ,

whence 
$$\frac{[\text{Hb}^-]}{\text{Total Hb}} = \frac{K_R}{K_R + \text{H}^+}.$$

On the basis of the same considerations as those just given for  $K_O$ ,  $K_R$  is taken as  $10^{-8.5}$  and  $p_{K_R} = 8.5$  at  $18^\circ$ .

$K$  = ionisation constant of the weak acid constituent of the foreign buffer  
 =  $10^{-6.80}$  at  $18^\circ$  for phosphate buffer ( $M/15$ )  
 =  $10^{-9.20}$  at  $18^\circ$  for borate buffer ( $M/6$ ),

$Q_{110}$  = heat of the reaction  $\text{O}_2 + \text{Hb}^- \rightarrow \text{O}_2\text{Hb}^- = 13,400$  cals.

From the numerical values assigned to  $K_O$  and  $K_R$  it follows that at  $p_{\text{H}} > ca. 9.5$ , both reduced and oxyhaemoglobin are almost entirely in the oxy-labile ionised form.  $Q_{110}$  is therefore given by the average of the results at  $p_{\text{H}}$  ca. 9.5 in Table II, viz. 13,400 cals.

$Q_{110}$  = heat of the reaction  $\text{O}_2 + \text{Hb} \rightarrow \text{O}_2\text{Hb}$ , assumed = 11,400 cals. For the reduced and oxyhaemoglobin to be both entirely in the oxy-labile unionised form, it would be necessary to work at  $p_{\text{H}} < 5.0$ , which is unfortunately too high an acidity for the heat of reaction to be measured directly owing to the difficulty of avoiding methaemoglobin formation under these conditions. The value of 11,400 cals. is one which gives a satisfactory fit between the observed results of Table II and those calculated by the theoretical method which follows.

$Q_{\text{H}}$  = heat of combination of 1 g. ion of H with haemoglobin whether in the oxy-labile position or elsewhere = 9000 cals. (average of values given later).

Stadie and Martin [1924] have given reasons for believing that the heat of combination of the oxy-labile H ion with haemoglobin is the same as the heat of combination of other H ions.

$Q_A$  = heat of ionisation of foreign buffer  
 = 1000 calories for phosphate buffer  
 = 4000 calories for borate buffer.

The buffer power symbols are given later.

Before proceeding to the theoretical calculation it is necessary to refer to the titration curve of haemoglobin, by which is meant the amount of alkali neutralised per equivalent of haemoglobin at varying  $p_{\text{H}}$ . In Fig. 4 based on Peters and Van Slyke [1931, p. 538] are plotted three titration curves, of which  $OO'$  is for oxyhaemoglobin.

$RR'$  is for reduced haemoglobin.

$XX'$  is the curve calculated for those ionisable groups of the oxyhaemoglobin or the reduced haemoglobin molecule, which are not affected by oxygenation, and which in contradistinction to the oxy-labile part of the molecule may be called the "oxy-stable" residue.

The curve  $XX'$  is obtained by subtracting the proportion of reduced haemoglobin which is in the oxy-labile ionised form at each  $p_H$ , i.e. a quantity  $= \frac{K_R}{K_R + H^+}$ , from the ordinate of the point on curve  $RR'$  at that  $p_H$ . Exactly the same curve  $XX'$  is obtained by subtracting, from  $OO'$ , the amount of oxyhaemoglobin which is in the oxy-labile ionised form at each  $p_H$ , i.e.  $\frac{K_O}{K_O + H^+}$  per equivalent of haemoglobin.

Fig. 4. Titration curves of oxyhaemoglobin, reduced haemoglobin and "oxy-stable residue" of haemoglobin at temperature  $18^\circ$  (calculated from data of Hastings *et al.* [1924], and Stadie and Martin [1924]).

The curves plotted in Fig. 4 are for a temperature of  $18^\circ$  and so are each shifted  $0.5 p_H$  unit to the alkaline side of the corresponding curves given by Peters and Van Slyke, which are for  $38^\circ$ . This correction for the change of temperature is based on Stadie and Martin's data [1924]. In computing the oxy-stable titration curve,  $K_O$  has been taken  $= 10^{-7.0}$  and  $K_R = 10^{-8.5}$ .

Let  $\beta_O$  = buffer power of oxyhaemoglobin at each  $p_H$   
 = the tangent of the angle made with the  $p_H$  axis by the tangent to the titration curve at each  $p_H$ .

$\beta_R$  = similarly the buffer power of reduced haemoglobin,

$\beta_S$  = buffer power of the oxy-stable residue of oxygenated or reduced haemoglobin.

Let the point  $R'$  in Fig. 4 correspond to the condition of the haemoglobin solution when in the reduced state.

Let the point  $O$  in Fig. 4 correspond to the condition of the haemoglobin when oxygenated.

*Method of calculation.*

We shall now show how to calculate for the general case the heat liberated when one equivalent of haemoglobin is oxygenated. This involves:

(i) Oxygenation of  $\frac{K_R}{K_R + H}$  equivalents of oxy-labile ionised reduced haemoglobin to  $\frac{K_R}{K_R + H'}$  equivalents of oxy-labile ionised oxyhaemoglobin.

$$\text{Heat liberated} = Q_{Hb} \frac{K_R}{K_R + H'}$$

(ii) Oxygenation of  $\frac{H'}{K_R + H'}$  equivalents of oxy-labile unionised reduced haemoglobin to  $\frac{H'}{K_R + H'}$  equivalents of oxy-labile unionised oxyhaemoglobin.

$$\text{Heat liberated} = Q_{Hb} \frac{H'}{K_R + H'}$$

(iii) Unionisation of  $\left( \frac{H'}{K_R + H'} - \frac{H}{K_O + H} \right)$  equivalents of oxy-labile unionised oxyhaemoglobin.

$$\text{Heat absorbed} = Q_H \left( \frac{H'}{K_R + H'} - \frac{H}{K_O + H} \right)$$

As a result of processes (i), (ii), (iii) the oxyhaemoglobin is now at equilibrium between the oxy-labile ionised and unionised forms at hydrogen ion concentration,  $H$ , but there have been liberated  $\left( \frac{H'}{K_R + H'} - \frac{H}{K_O + H} \right)$  g. ions of hydrogen. Of these

(iv)  $\beta_s (p_H' - p_H)$  combine with the oxy-stable residue of the oxyhaemoglobin molecule.

$$\text{Heat liberated} = Q_H \beta_s (p_H' - p_H)$$

(v)  $\left( \frac{KA}{H' + K} - \frac{KA}{H + K} \right)$  are taken up by the foreign buffer.

$$\text{Heat liberated} = Q_A \left( \frac{KA}{H' + K} - \frac{KA}{H + K} \right)$$

If there is no foreign buffer present, the heat evolved in process (iii) is almost exactly counterbalanced by that evolved in process (iv), and since there is no heat evolved by process (v), the overall heat will be simply the sum of the heats due to processes (i) and (ii), i.e.

$$\text{Overall heat} = Q_{Hb} \frac{K_R}{K_R + H'} + Q_{Hb} \frac{H'}{K_R + H'} \quad \dots\dots(1).$$

But if there is foreign buffer present, the overall heat

$$\begin{aligned} &= Q_{Hb} \frac{K_R}{K_R + H'} + Q_{Hb} \frac{H'}{K_R + H'} - Q_H \left( \frac{H'}{K_R + H'} - \frac{H}{K_O + H} \right) + Q\beta_s (p_H' - p_H) \\ &\quad + Q_A \left( \frac{KA}{H' + K} - \frac{KA}{H + K} \right) \quad \dots\dots(2). \end{aligned}$$

The relation between the  $p_H$  before and after oxygenation is given by the equation

$$\left( \frac{H'}{K_R + H'} - \frac{H}{K_O + H} \right) = \beta_s (p_H' - p_H) + \left( \frac{KA}{H' + K} - \frac{KA}{H + K} \right) \quad \dots\dots(3),$$

so that if the various numerical constants, together with the  $p_H$  after oxygenation, are known, the  $p_H$  before oxygenation can be calculated. From equations (2) and (3) the total overall heat  $Q$

$$= Q_{Hb} \frac{K_R}{K_R + H'} + Q_{Hb} \frac{H'}{K_R + H'} + (Q_A - Q_H) \left( \frac{KA}{H' + K} - \frac{KA}{H + K} \right) \quad \dots\dots(4).$$

Equations (2), (3) and (4) have been used for numerical calculations of the overall heat of reaction under the various conditions which have so far been studied.

Table III gives the calculated results for haemoglobin of concentration = 0.01 equivalent/litre:

(i) In  $M/15$  phosphate buffer  $p_{\text{H}}$  6.67 and  $p_{\text{H}}$  7.0.

(ii) In  $M/6$  borate buffer  $p_{\text{H}}$  7.6.

According to the writer's measurements with the glass electrode the  $p_{\text{H}}$  of blood, treated with 1% boric acid and then rendered  $\text{CO}_2$ -free by repeated evacuation and shaking, is on the average 7.6 at  $18^\circ$ . Such boric acid blood was extensively used by Brown and Hill [1923], and so it seemed of interest to apply the calculations to haemoglobin solutions of corresponding condition.

(iii) With no foreign buffer added,  $p_{\text{H}}$  8.4.

According to the glass electrode measurements this is the average  $p_{\text{H}}$  at  $18^\circ$  reached by whole blood when rendered practically  $\text{CO}_2$ -free by repeated evacuation and shaking.

It may be remembered that Brown and Hill made some measurements on this kind of blood also.

Table III.

Conc. of Hb in equiva- lents/litre	Nature and conc. of foreign buffer	$p_{\text{H}}$	$p_{\text{H}}'$	$\beta_{\text{S}}$	Direct heat
0.01	$M/15$ phosphate	6.67	$\begin{cases} 6.715 \\ 6.728 \end{cases}$	$\begin{cases} 2.0 \\ 1.2 \end{cases}$	$\begin{cases} 9,930 \\ 9,710 \end{cases}$
0.01	$M/15$ phosphate	7.0	$\begin{cases} 7.083 \\ 7.097 \end{cases}$	$\begin{cases} 2.0 \\ 1.2 \end{cases}$	$\begin{cases} 9,120 \\ 8,700 \end{cases}$
0.01	$M/6$ borate	7.6	$\begin{cases} 7.778 \\ 7.825 \end{cases}$	$\begin{cases} 2.0 \\ 1.2 \end{cases}$	$\begin{cases} 10,680 \\ 10,410 \end{cases}$
0.01	No foreign buffer added; freed from $\text{CO}_2$ by evacuation	8.4	—	—	12,600
0.01		10.0	---	—	13,400

The figures of Table III thus cover the most important cases dealt with by Brown and Hill [1923] and by Table II of this paper. The values of the heat are calculated both for  $\beta_{\text{S}}=2$ , this being the value given by Van Slyke's titration curve data for horse haemoglobin, and for  $\beta_{\text{S}}=1.2$ , there being some experimental evidence that the buffer value of ox haemoglobin may be appreciably less than that of horse haemoglobin, perhaps as much as one-third less. With haemoglobin of a lower buffer power the overall heat of reaction is somewhat less, as would be expected.

The heat of reaction for haemoglobin in  $M/15$  phosphate buffer  $p_{\text{H}}$  ca. 6.8, comes out at about 4000 calories less than the value in the alkaline range, as has indeed been shown experimentally in Table II. If  $Q_{\text{Hb}}$  had been assumed to be the same as  $Q_{\text{Hb}}$ , viz. 13,400 calories instead of being assumed to be 2000 calories less, the calculated difference in the two overall heats would have amounted only to 2000 calories, instead of 4000 calories. Although there is some uncertainty in the calculations owing to lack of knowledge as to the values of  $K_{\text{O}}$ ,  $K_{\text{R}}$  and  $\beta_{\text{S}}$  for the particular ox haemoglobin solutions used, it still seems impossible to account for so large a difference between the value of the heat in alkaline solution and the value of the heat at  $p_{\text{H}}$  6.8 in presence of phosphate buffer, without postulating that the heat of the primary reaction between oxygen and haemoglobin in acid solution, i.e.  $Q_{\text{Hb}}$ , is appreciably less than the heat of the reaction  $Q_{\text{Hb}}$  in alkaline solution. This is a new conclusion, which it is hoped to test out further by other methods.

Brown and Hill [1923] noted that the heat of reaction of oxygen with 1% boric acid blood was about 3000 calories less than the heat of reaction with

CO<sub>2</sub>-free blood containing no added foreign buffer. As regards haemoglobin solution, the calculated difference according to Table II is about 2000 calories. Brown and Hill's heat data may, however, be too high (*v. infra*); furthermore the ratio of haemoglobin concentration to boric acid concentration in their 1% boric acid blood may have been less than in the case quoted in Table III—this also would have tended to make their observed difference greater than the calculated one.

According to the theory put forward above, the minimum value for the overall heat of the reaction should occur when the  $p_H$  is midway between  $p_{K_1}$  and  $p_{K_2}$  and there is present a high concentration (relative to the haemoglobin) of a foreign buffer with a low heat of ionisation, *e.g.* phosphate buffer. In such a case the overall heat of reaction might be expected to be nearly 7000 calories less than the value in alkaline solution. Unfortunately it is not easy to obtain these conditions without having the absolute concentration of haemoglobin too low for accurate measurements of the heat of reaction. This is the reason why the test has not yet been made, though it is hoped to carry it out with an improved apparatus in the near future.

*The heat of combination of H ions with haemoglobin.* This is an important figure in the above theory. Adair *et al.* [1929] have reviewed and discussed the data obtained up till that date and have, moreover, suggested that the heat may decrease as the  $p_H$  is lowered towards the isoelectric point of haemoglobin. Two preliminary experiments were therefore performed to test this point as regards purified ox haemoglobin:

By a modification of the technique described previously, small portions of acetic acid or acetic acid-sodium acetate buffer were mixed with haemoglobin solution, the heat recorded and the  $p_H$  measured before and afterwards by means of the glass electrode. Allowance was made for the slight heat of ionisation of acetic acid. The results obtained are shown in Table IV. The values of the

Table IV

$p_H$ range	Heat in calories per g. ion H combining
1st sample of { 8.75-8.0 haemoglobin { 8.0-7.1	9700 9500
{ 7.1-6.45	9800
2nd sample of { 8.4-7.35 haemoglobin { 7.35-6.25	8500 8200

heat given in Table IV do not show any marked decline with increased acidity, but the measurements were not very accurate, and further work is needed. The average of the figures reviewed by Adair *et al.* [1929] and obtained since then by Roughton [1930, 1, 2 and Table III of the present paper] is about 9000 calories. The latter value has therefore been used for the calculations given in this paper.

## DISCUSSION.

*Comparison with the results of previous workers.* Adolph and Henderson's [1922] figures show such a wide scatter that it is hardly possible to compare our results with theirs. Only a few of our experiments were done under nearly the same conditions of  $p_H$  and buffer content as were those of Brown and Hill [1923] but the general tendency of our figures is to be somewhat lower, *i.e.* 1000-2000 calories, than theirs. No systematic comparison was, however, projected, since

Brown and Hill measured the oxygen taken up by the blood with the aid of the Barcroft-Haldane methods of blood gas analysis. As already mentioned these are known now to give results which are often too low, which would mean that the values for the heat of combination of 1 g. mol.  $O_2$  with haemoglobin given by Brown and Hill would be too high, and to an unknown extent.

None of the results given in this paper or found at any stage in our work approached the high value of 28,000 calories recorded by Barcroft and Hill [1909]. Figures of the same order were, however, found by Macela and Seliškar [1925], using the indirect method (*i.e.* effect of temperature on the dissociation curve): the ratio of the temperature coefficient of the rate of dissociation of oxyhaemoglobin to that of the rate of combination of oxygen with haemoglobin, as reported by Hartridge and Roughton [1923, 2], also suggest a heat value of this order. No explanation has as yet been given of these anomalous results: it is possible that the tendency towards a high heat value may be associated with the same obscure factor, which spasmodically causes the dissociation curve of mammalian oxyhaemoglobin to be hyperbolic instead of sigmoid in shape.

*Theoretical conclusions.* The data obtained in this paper show that the thermochemistry of the reaction between oxygen and haemoglobin is straightforward in certain points, which had not previously been tested, namely in that the heat per g. mol.  $O_2$  combining with haemoglobin is independent of the percentage saturation, the purity and the habitat of the haemoglobin (*i.e.* whether it is present in solution or in the red blood corpuscle). The thermochemical measurements thus give no crucial evidence either for or against the intermediate compound hypothesis of Adair, nor do they give any indication that the condition of haemoglobin in the corpuscle is different from its condition in solution.

As regards the effect of  $p_{H^+}$  and foreign buffer content a more comprehensive theory has been worked out than that of Brown and Hill [1923], who did not, through lack of knowledge of the titration curves of oxygenated and reduced haemoglobin (which at that time had not yet been worked out), realise that oxy-labile H ions liberated from one part of the haemoglobin molecule would be buffered, not only by the foreign buffers in the solution (*i.e.* substances other than haemoglobin), but also by other parts of the haemoglobin molecule itself. The present theory needs more extensive test than it has yet received, especially as regards the interesting point that the heat of reaction of oxygen with haemoglobin in the unionised condition is appreciably less than in the ionised condition.

In broad outline, the thermochemistry of the oxygen-haemoglobin reaction, has probably been now almost fully worked out, without having thrown the new light on the mechanism of the  $O_2$ -haemoglobin reaction, which the earlier workers in this field had hoped to obtain thereby. The knowledge gained, however, is of value, not only for its own sake, but also as a basis for studying the thermochemistry of the closely connected reactions of  $CO_2$  in blood. This subject, hitherto but little explored, we hope shortly to take up in detail in the hope of elucidating further some of the more newly recognised processes in  $CO_2$  transport in the blood, especially those in which the enzyme, carbonic anhydrase, on the one hand and carbamino-compounds on the other are concerned.

#### SUMMARY.

1. A differential calorimeter is described for the measurement of the heat evolved when blood or haemoglobin solution is shaken with various amounts of gaseous oxygen or carbon monoxide. The technique has been applied to certain outstanding points in the thermochemistry of the haemoglobin reactions.

2. The heat of combination of haemoglobin, per g. mol. of oxygen, as measured directly is:

(a) independent of the percentage saturation over the range investigated, viz. 25–80 %; this also holds good for the heat of combination of haemoglobin with carbon monoxide;

(b) practically the same in whole blood, laked blood and purified haemoglobin;

(c) much greater at  $p_{\text{H}}$  ca. 9.5 (i.e.  $Q = 13,400$  calories about) than at  $p_{\text{H}}$  6.8,  $M/15$  phosphate buffer (i.e.  $Q = 9400$  calories about). The difference is in part due to the heat of combination of oxygen with oxy-labile ionised haemoglobin being greater than the heat of combination with "oxy-labile" unionised haemoglobin, and partly due to the heat effects associated with the secondary ionic reactions, which occur over the  $p_{\text{H}}$  range 6.0–9.0. The magnitude of these effects depends not only on the  $p_{\text{H}}$  but also on the nature and concentration of the foreign buffer (phosphate) relative to that of the haemoglobin. Detailed theory and calculations concerning this effect are given.

Part of the expenses of these researches was defrayed by the Medical Research Council, to whom I desire to express my thanks. I am also indebted to Dr D. M. Greenberg for his assistance in the preliminary stages of the calorimetric experiments.

# CCCXI. THE TIME COURSE OF THE HEAT EFFECTS IN RAPID CHEMICAL CHANGES.

## I. IMPROVED APPARATUS AND METHODS.

## II. THE REACTIONS OF HAEMOGLOBIN WITH OXYGEN AND CARBON MONOXIDE.

BY JOHN BURRASTON BATEMAN<sup>1</sup>  
AND FRANCIS JOHN WORSLEY ROUGHTON.

*From the Physiology Laboratory, Cambridge.*

*(Received October 1st, 1935.)*

ROUGHTON [1930, 1, 2] has described a method of following the heat effects in rapid chemical changes and has applied it to the reactions of acids and alkalis with buffers, amino-acids and proteins. The principle of the method is as follows.

The two substances which are to react are contained in separate solutions *R* and *L*; reaction between them is brought about by driving the two fluids into a special mixing chamber, wherein mixture occurs in 1/1000 sec. or less. The mixed fluid emerging from the mixing chamber passes into an observation tube, at various points in which the temperature of the running fluid is taken by means of a thermocouple. The change in temperature due to the reaction between *R* and *L* is given by the difference between the reading with both fluids running and the average of the two readings when *R* and *L* are running separately. The corresponding time is simply equal to  $d/v$ , where  $d$  is the distance from the mixing chamber of the thermojunction and  $v$  is the rate of flow of the mixed fluid down the observation tube.

This method was developed to the extent of being able to measure, to within about 0.001°, the temperature change occurring in rapid reactions within 0.01 sec. or less from the beginning of such reactions. Roughton, however, pointed out that many, if not most, of the rapid chemical reactions which are of interest to the biochemist only involve changes, *in toto*, of 0.01–0.001°. Hence, if the course of these changes is to be followed accurately, the sensitivity of the method must be increased 5 or 10-fold, *i.e.* to within 0.0001–0.0002°. This objective has been realised in the papers presented below. Of these, Part I deals with the changes in apparatus and technique by which the greater sensitivity has been reached, whilst in Part II will be found some preliminary results of the method in regard to the reactions of haemoglobin with oxygen and carbon monoxide.

## I. IMPROVED APPARATUS AND METHODS.

### DESCRIPTION OF APPARATUS.

*General arrangement of apparatus.* The refinements outlined by Roughton [1930, 1] for a ten-fold increase in sensitivity, and those actually carried out in the present apparatus, consisted mainly in the improved thermal control of the entire apparatus, thus enabling a slower galvanometer of about 7 times greater sensitivity to be used. The 5 mm. observation tube of the previous paper was

<sup>1</sup> George Henry Lewes Student.

replaced by one of 2 mm. diameter: for a given rate of linear flow down the tube, the consumption of fluid is reduced to about one-sixth, thus giving more time for the taking of each individual galvanometer reading without undue sacrifice of fluid.

The general arrangement is shown in Fig. 1. The reagents are placed in stoneware bottles, *R* and *L*, of about 5 l. capacity, mounted symmetrically on a metal stand, and each connected in the manner shown in a vertical metal box *B*, containing the mixing chamber and observation tube and mounted on the same stand. The entire stand, with its bottles and metal box, is immersed in a 70-gallon tank containing water, which can be kept constant in temperature to  $\pm 0.01^\circ$  (as checked by a Beckmann thermometer) by a small lamp turned on and off occasionally by hand and by vigorous stirring with compressed air. The apparatus is raised from (or lowered into) the tank, as required, by means of a block and tackle.

Fig. 1. Apparatus for determination of velocity of rapid reactions.  
(For description see text.)

*The reagent bottles, R, L.* These were drilled at the top for the introduction of two or more glass inlet tubes, *i*, which are sealed in with tightly fitting rubber tubing, and the joints made rigid by means of metal collars filled with a cement of wax and resin. One of these inlet tubes passes to the bottom of the bottle and can be used to introduce the reagents or to withdraw samples of fluid during an experiment. The other is short and serves as an inlet for the compressed gas which is to force the reagent into the mixing chamber. This gas is brought to the same temperature as the reagents by being passed through 80 ft. of lead tubing lining the inside of the thermostat before it enters the bottle. Since in the present apparatus the gas only comes in contact with the upper layers of the reagent, and since the reagent is forced out at the bottom of the bottle less care need be taken than in the previous work as to the heat effects accompanying the sudden compression and/or the humidity of the gas.

Additional holes in the necks of the bottles can be used as points of entry for the various thermocouples used to indicate the difference in temperature between the reagents and the thermostat water, or between the contents of *R* and *L* respectively. Small adjustments of temperature, just before a run, can be made by adding warm water to the bath, or by heating one or other of the fluids in *R* and *L* by means of 3-watt electric bulbs *w*, suitably protected from water and sealed into the bottom of the bottles.

The reagents are stirred by stout glass rods, *g*, bent and flattened into vanes at their free ends, the rods being introduced through lanoline-lubricated ground

joints, *j*, fixed in rubber corks in the necks of the bottles. The glass rods are coupled at their top ends to the shaft of special electric motors by rubber tubing, and are rotated about 90 times a minute. This arrangement, which proved satisfactory in every way, enables the solutions to be stirred effectively when the bottles contain any gas other than air. This condition had to be met in our work on haemoglobin (in Part II).

*The metal box B and its contents.* The glass leads, *l*, which connect the lower parts of the bottles with the mixing chamber, are much shorter than the delivery tubes in the previous apparatus. They are air-jacketed by wide rubber tubing between the bottles and the metal box.

The mixing chamber and the observation tube are themselves situated symmetrically in the water-tight metal box *B*, the detachable front of which is fixed in place by wing-nuts. The flow of reagents into the mixing-chamber is controlled from the outside by brass rods, *r*, which pass through the roof of *B* and rest, at their lower ends, on short pieces of rubber tubing, *t*, inserted in the connections on either side of the mixing chamber and supported underneath by brass blocks.

The mixing chamber, *m*, is a simple three-way tap of suitable bore, its central limb being sealed as regularly as possible to the lower end of the observation tube.

The observation tube, *o*, a glass capillary of internal diameter 2 mm. and length 12 cm. is widened at the top so as to join with a few cm. of 10 mm. diameter tubing, and then passes through the roof of the box to a funnel from which the effluent can either be sucked to waste or collected in an evacuated tonometer.

*Construction of thermocouples.* These were made from enamelled wire, no. 24 copper and no. 32 constantan, roughly as described in the previous paper, and then insulated with several layers of celluloid varnish. They were introduced into the observation tube from above *via* the open funnel. Two types of thermocouple were again used: (*a*) The "absolute" or "thermos" type in which one of the junctions is placed in the observation tube and the other, the "cold" one, is kept in a suitable enclosure, constant to  $\pm 0.0002^\circ$  during the period of the experiment. In the first experiments, the cold junction was immersed in a cylinder consisting of alternate layers of copper and paraffin wax, in the metal box *B*, whilst in subsequent ones it was placed in a small vessel of mercury separated by an air gap from the walls of a large bottle immersed in the thermostat, the latter arrangement being more convenient. (*b*) The "differential" type, in which the junctions are only 3 cm. apart, and which therefore measures the difference of temperature between two points 3 cm. apart in the running fluid. As before, and as was indeed to be expected, this type proved much more satisfactory, both as regards the steadiness and the speed of response of the galvanometer reading.

*Electrical connections, galvanometer etc.* The copper leads from the thermocouples were soldered to rubber-covered copper cable leads, which were connected *via* appropriate "all-copper" switches and a manganin resistance box with the galvanometer.

For the present purpose sufficient sensitivity was given by a Kipp Zb moving coil instrument, shunted with 50 ohms and with minimum magnetic control. With the scale at 4 metres, the deflection per micro-volt with 0 ohms in series was about 120 mm., so that the accuracy attainable on the electrical side, if the deflections be read to 0.2 mm., is better than  $0.00004^\circ$ .

*Calibration of thermocouples.* Readings were usually taken either with 50 ohms or 0 ohms in series with the couple and the galvanometer. In the former case the

couples were calibrated by inserting the junctions in separate flasks, which were filled with well-stirred water at temperatures differing respectively from one another by 1 or 2°. The calibration with 0 ohms in series was not made directly, since it would have needed too small a temperature difference between the two flasks to be measured accurately with ordinary standard thermometers: instead it was calculated from the calibration with 50 ohms in series by the formula:

$$\theta_0 = \theta_{50} \times (50 + T + G)/(T + G),$$

where  $\theta_0$ ,  $\theta_{50}$  are the sensitivities of the galvanometer, with 0 and 50 ohms respectively in series;  $T$  is the resistance of the thermocouple,  $G$  is the resistance of the galvanometer and its leads, both of which were determined independently.

#### TYPICAL EXPERIMENT AND CONTROLS.

##### *Control experiment with plain water in bottles R and L.*

Roughton [1930, 1] pointed out that the method contained several physical sources of error, which might have to be allowed for by blank corrections. Of these the most important are fluid friction, heat conduction between the flowing fluids and their surroundings and local temperature effects in the neighbourhood of the thermojunctions. Theoretical calculation and experimental controls, however, both showed that the temperature effects due to these physical sources of error were individually and collectively within the range 0.0001–0.001°, and hence could be neglected in the previous work, since the accuracy there aimed at was only 0.001°. In the present work, with its hope of a five- or ten-fold increase in sensitivity, the effects had obviously to be investigated further: this was done, as before, by control experiments with plain water in each bottle. Since the procedure was the same as in ordinary experiments, in which positive thermochemical effects were to be looked for, it will be useful, at the outset, to describe it in detail.

At least 2 hours before the experiment was to begin, bottles *R* and *L* were each filled with 4 litres of water. The apparatus was lowered into the thermostat and kept there until the time of the experiment, the liquids being stirred periodically, and their temperatures brought to that of the bath water (to within  $\pm 0.001^\circ$ ) by suitable short periods of electric heating. The pressure inside the bottles was increased to 20 cm. Hg above atmospheric pressure by connecting the gas leads of *R* and *L* to a cylinder of compressed oxygen or nitrogen *via* the 80 ft. length of tubing in the thermostat, the pressure being regulated automatically by a simple mercury blow-off valve. Stirring of the bath and reagent bottles was stopped, and, after the differential thermocouple had been placed in a suitable position in the observation tube the switch connecting it to the galvanometer was pressed down; this was done as early as possible before the beginning of the measurements, so as to allow time for the "parasitic" E.M.F.'s of the circuit to become stable. A series resistance of 10,000 ohms and a short-circuiting switch protected the galvanometer during the adjustment of the thermocouple. The series resistance was then reduced to zero (or in certain experiments to 50 ohms) and readings taken in the following sequence:

- (i) Fluid from *R* alone running for 20 sec. Galvanometer scale reading taken =  $R_1 = 515.0$  mm.
- (ii) Fluid from both bottles running together for 20 sec. Reading =  $B = 515.5$  mm.
- (iii) Fluid from *L* alone running for 20 sec. Reading =  $L = 514.2$  mm.

In this example the two junctions of the thermo-couple were placed at 2 and 5 cm. respectively from the mixing chamber. Let  $x$  = relative delivery of  $R$  to  $L$  when both are running (*v. infra*). Then temperature effect, due to physical causes, is thus, in the case of the differential thermocouple

$$= B - \frac{xR + L}{x + 1} = 0.9 \text{ mm.} = 0.00022^\circ \text{ (warming).}$$

Actually in this example, and indeed in general, readings  $R$  and  $L$  are so close that  $\frac{xR + L}{x + 1}$  can with sufficient accuracy be replaced by  $\frac{1}{2}(R + L)$ , provided, as is usually the case, that  $x$  lies between 0.4 and 0.6.

The same procedure was then repeated with the differential thermocouple in 2 or 3 other positions.

By that time sufficient fluid had passed through the leads and the mixing-chamber for them to reach a much more steady temperature state than at the start. The differential couple was then replaced by the "absolute" couple, the latter usually being adjusted in the middle of the capillary part of the observation tube, *i.e.* at 5 cm. from the mixing chamber. The absolute "couple" is of course affected by temperature drifts in the contents of the bottles during the experiment; to compensate for these a set of five readings was always made in the following order:

- (i) Fluid from  $R$  alone for 20 sec. Reading =  $R_1 = 372.2$  mm.
- (ii) Fluid from both bottles for 20 sec. Reading =  $B_1 = 367.2$  mm.
- (iii) Fluid from  $L$  alone for 20 sec. Reading =  $L = 365.3$  mm.
- (iv) Fluid from both bottles for 20 sec. Reading =  $B_2 = 364.9$  mm.
- (v) Fluid from  $R$  alone for 20 sec. Reading =  $R_2 = 369.5$  mm.

If the solutions had not been adequately equilibrated as regards temperature, the 20-sec. running period had to be increased.

The temperature effect, due to physical causes, is for the "absolute" couple

$$\text{thus} \quad = \frac{1}{2}(B_1 + B_2) - \frac{x(R_1 + R_2)/2 + L}{1 + x} = -1.8 \text{ mm.} = 0.0006^\circ \text{ (warming).}$$

In this case also, readings  $R$  and  $L$  were so close together, that the expression

$$\frac{x(R_1 + R_2)/2 + L}{1 + x}$$

could be replaced by

$$\frac{(R_1 + R_2)/2 + L}{2}$$

As a rule the readings were less steady than the differential couple readings, especially if the absolute readings were, in contradistinction to the above procedure, taken before much fluid had been passed through the apparatus.

To obtain the rate of flow, the mixed fluid emerging into the funnel during 15 sec. run was collected in an evacuated tonometer and measured. The rate usually varied from 500 to 700 ml. per minute according to the position of the thermocouple in the observation tube. Allowance had to be made for this in calculating the respective time intervals.

In this control experiment it was not necessary to know the relative delivery of  $R$  to  $L$  with both fluids running together, *i.e.*  $x$ , since readings  $R$  and  $L$  were so close together. In "live" experiments, however, the relative delivery is always required whether  $R$  and  $L$  are close or not: in experiments with haemoglobin solution, it was calculated simply from the ratio of the respective Hb concentrations in the mixed fluid and in fluid  $L$  (assuming that the haemoglobin was placed in this bottle and not in  $R$ ) as estimated colorimetrically: in all other

experiments, so far, one or both of the reagents has been capable of volumetric estimation (*e.g.* HCl, NaHCO<sub>3</sub> or NaOH). In these cases also,  $x$  can easily be calculated from the respective titres of the mixed fluid and of the original reagents  $R$  and  $L$ . If neither solution is naturally coloured or titratable, the simplest plan is to add a small amount of an indifferent coloured substance to  $L$  and to calculate the relative delivery by the same colorimetric method, as in the case of haemoglobin solutions.

#### *Magnitude of blank errors.*

These were measured by control experiments with plain water (or aerated blood solution) in bottles  $R$  and  $L$ .

(a) *With the differential thermocouple.* In size the blank effect shown in the control experiment above is of the order to be expected, namely 0.0002–0.0003°. The consistency is shown by the figures of Table I: from these it appears that the heat effects at specified points in the observation tube repeat themselves to within 0.1 mm. (*i.e.* 0.000025°), even when one of the bottles contains blood diluted 1 in 4, instead of water. Corresponding blank corrections have therefore been deducted from the differential couple readings in “live” experiments, and the residue, if any, attributed to temperature differences of thermochemical origin.

Up to a distance of 11 cm. from the observation tube the distal junction is seen to be 0.0002–0.0003° hotter than the one proximal to the mixing chamber: this is probably due, in the main, to the frictional resistance encountered by the fluid in travelling from one junction to the other and dissipated as heat. In the 11–14 position, however, the situation is reversed: this is probably to be explained by the fact that the observation tube widens out at a distance between 11 and 14 cm. from the mixing chamber, which means that at the 11 cm. point the fluid must be travelling much faster than at the 14 cm. point. The diminished “local turbulence” and drop of pressure in the neighbourhood of the latter probably account for its being apparently cooler by 0.00035° than the 11 cm. point.

Table I. *Test for blank corrections with differential thermocouple.*

Series resistance in circuit = 0 ohm.				
Driving pressure applied to $R$ and $L$ = 20 cm. Hg air pressure.				
Distance of differential junctions from mixing chamber (in cm.)	2–5	5–8	8–11	11–14
Heat effect in mm. galv. deflection:				
(a) Water + water	+ 0.8	+ 1.4	+ 1.7	- 1.5
(b) Water + blood solution (1 in 4)	+ 0.9	+ 1.4	$\left\{ \begin{array}{l} + 1.4 \\ + 1.4 \end{array} \right.$	$\left\{ \begin{array}{l} - 1.5 \\ - 1.25 \\ - 1.4 \end{array} \right.$

1 mm. = 0.00025°.

Here + means that junction distal to mixing chamber is warmer.

Here - means that junction distal to mixing chamber is cooler.

(b) *With the absolute thermocouple.* The blank corrections for the absolute thermocouple in various positions in the observation tube are shown by the figures given in Table II. Consistent results were obtained in two separate experiments. The corrections turn out, not unexpectedly, to be distinctly greater than those for the differential thermocouple but are, from the physical point of view, quite reasonable in size. A specially extended series was taken with the thermocouple at 5 cm., since this was the staple position used in most of our experiments. The mean effect at this position = 2.1 mm. galv. deflection = 0.00067°.

Table II. *Test for blank corrections with absolute thermocouple.*

Fluid $R$ = fluid $L$ = tap water.			
Series resistance in circuit = 0 ohm.			
Driving pressure = 20 cm. Hg.			
Relative deliveries of two fluids equal.			
Distance of absolute junction from mixing chamber in cm.	2	5	8
Heat effect in mm. galv. deflection:			
(a) Water + water	$\begin{cases} +2.3 \\ +2.3 \end{cases}$	+1.9	$\begin{cases} +1.6 \\ +1.8 \end{cases}$
(b) Water + water	—	$\begin{cases} +1.8 \\ +2.3 \\ +2.0 \\ +2.4 \end{cases}$	+2.5
1 mm. = 0.00032°.			

Here + means that reading  $B$  is warmer than the mean of readings  $R$  and  $L$ .

#### *Accuracy of the method and résumé of procedure.*

With total temperature changes of 0.05° or more in the observation tube, the measurements are believed to be accurate to within about 1 % of the total change, as was the case in Roughton's earlier work. In the case of the smaller changes, of the order of 0.005–0.01°, which it was the special object of this work to measure, a higher "absolute" accuracy was reached, especially with the differential thermocouple. This is shown by

*The degree of agreement between duplicates.* Table III shows a series of duplicate determinations made both with the differential and the absolute thermocouples. In the case of the differential couple, duplicates usually agreed with one another to within the limit to which the galvanometer deflections could be read by eye, *i.e.* to 0.12 mm. = 0.00003°. In the case of the absolute couple the divergence was naturally much greater, but did not on the average exceed 0.00026°. It is probable that a single set of observations with the absolute thermocouple is as a rule correct to 0.0002°, when the total temperature change is less than 0.01°; with the differential couple the accuracy seems to be about five times better, *i.e.* to within 0.00004°.

Table III. *Duplicate readings of difference between temperature of mixed fluid and average temperature of separate fluids  $R$  and  $L$ .*

Readings expressed in mm. galv. deflection. Series resistance in circuit = 0 ohm.

Differential thermocouple		Absolute thermocouple	
Reading 1	Reading 2	Reading 1	Reading 2
1.40	1.40	10.8	10.7
1.40	1.40	14.6	15.2
1.50	1.25	12.1	12.5
9.40	9.30	13.3	12.2
6.20	6.66	13.3	14.2
0.45	0.50	11.8	10.0

Average discrepancy between duplicates.

0.14 mm. = 0.00003°

0.80 mm. = 0.00026°.

That these claims are not exaggerated has been checked in two ways:

(i) *Comparison of the rate of combination of carbon monoxide with haemoglobin by the thermal and optical methods.* In these experiments, which are described

more fully in Part II, it was found that the rate of combination of CO with haemoglobin by the present method agreed to within 2% with the rate as measured independently by the optical method of Millikan [1933]. This degree of agreement could hardly have been attained if the thermal methods were appreciably less accurate than has just been claimed.

(ii) *Measurement by the absolute couple of the rapid heat of combination of HCl with NaOH.* Two experiments of this kind were made to test the accuracy and reliability of the absolute couple.

(a) Fluid  $R=0.0054\text{ }N\text{ HCl}$  (containing trace of  $\text{CO}_2$ ), fluid  $L=0.0214\text{ }N\text{ NaOH}$ .

Relative delivery of  $R$  to  $L=1/1.21$ .

Expected temperature rise  $=0.0343 \pm 0.0004^\circ$ .

Observed temperature rise  $=0.0340 \pm 0.0004^\circ$  (mean of two observations).

In this experiment, the total temperature change was too large for the maximum absolute accuracy to be expected.

(b) Fluid  $R=0.002\text{ }N\text{ NaOH}$ , Fluid  $L=0.00013\text{ }N\text{ HCl}$  (containing trace of  $\text{CO}_2$ ).

Relative deliveries of  $R$  and  $L$  equal.

Expected temperature rise  $=0.0008 \pm 0.0002^\circ$ .

Observed temperature rise  $=0.0009 \pm 0.0002^\circ$  (mean of 4 observations).

The uncertainties of 0.0004 and 0.0002 in the respective "expected temperature rises" in the two cases are due to the difficulty of estimating the concentration of such weak HCl solutions accurately. In both cases a small correction was inserted for the heat of neutralisation of the traces of dissolved  $\text{CO}_2$  in the HCl solution.

The agreement, on the whole, is quite as good as can be expected and we have hence felt justified in applying the method to the problems described in Part II, and to others since then.

#### *Résumé of procedure.*

For the convenience of the reader, the procedure in a typical "live" experiment may now be briefly recapitulated. The two reagents are placed in bottles  $R$  and  $L$  in the thermostat, and by a 2-hour period of appropriate stirring and electric heating are brought to within  $0.005^\circ$  of each other and the bath. This preliminary period may with advantage be prolonged to 4 hours or more. The solutions are then driven by compressed gas (pressure used  $=20\text{ cm. Hg}$ ) at the correct temperature into the mixing chamber in the sequence  $R$ , both,  $L$ , for periods of 20 sec. each, and the corresponding readings taken with the differential thermocouple at 2 or 3 different places in the observation tube. A set of readings with the absolute thermocouple, at say 5 cm. from the mixing-chamber, is then taken in the sequence  $R$ , both,  $L$ , for periods of 20 sec. each again. Further similar sets of readings with either of the thermocouples are then taken as desired.

The rate of flow is then measured, and the relative deliveries of  $R$  and  $L$  are calculated from the colour or titre of the mixed fluid, as compared with that of  $R$  and/or  $L$ . If neither  $R$  nor  $L$  possesses naturally a colour or titre, a small amount of an indifferent coloured substance may be added to one of them.

The above observations are then used to calculate the corresponding temperature differences, from which are subtracted blank corrections according to Tables I and II.

From these data it is easy to plot the thermochemical temperature change *versus* time from the beginning of the reaction. An example is shown in Fig. 2.

The interpretation of such temperature-time curves varies with the reaction under study, and no general rules can be laid down here. In computing the magnitude of the corresponding heat changes in calories, it has to be remembered that (i) the heat of dilution of the solutions on mixture may be significant, and in this case, if not obtainable from standard Tables, must be measured by special experiments, (ii) the specific heat of the mixed solution may differ from unity.

The apparatus of the present research can deal with time intervals, from mixture, of 0.005–0.5 sec. This range could, if desired, be extended both in an upward and downward direction.

#### *Forecast of further improvements.*

The limits of error of the temperature measurements are in the present apparatus much smaller than the size of the blank corrections for non-chemical sources of heat which there seems no way of avoiding. It therefore looks doubtful whether the temperature sensitivity can be developed much further, nor at the moment is there any call, since the apparatus with its existing accuracy has already a wide possible field of work before it. What, however, is badly needed is a radical economy in the quantity of the fluids required for an experiment, 4 litres being an outrageous, if not impossible, demand in many cases of biochemical interest. We hope, in due course, to address ourselves to this problem, but the solution of it would probably involve some rather radical changes in design: it may, therefore, not be attempted until the potentialities of the present technique shall have been more fully worked out.

## II. THE REACTIONS OF HAEMOGLOBIN WITH OXYGEN AND CARBON MONOXIDE.

Elsewhere Roughton [1935] describes measurements, by the usual slow calorimetric method, of the heat of combination of haemoglobin with oxygen and carbon monoxide. Reduced blood or haemoglobin solution was shaken with  $O_2$  or CO in thermos flasks, and the temperature of the contents was registered thermo-electrically at suitable intervals. Under these conditions 15 min., at least, were required for the temperature conditions to become steady again. This delay must have been in part due to the slowness of diffusion of  $O_2$  (or CO) from the gas phase to the haemoglobin in the liquid phase, and in part due to the slowness with which the heat, liberated by the reaction, was distributed throughout the contents and walls of the flasks. As to the actual rate of heat liberation itself these measurements gave no guide—the time so occupied might have been anything from 0.01 sec. to 5 min.

The measurement of the true speed at which the heat of these reactions is liberated is of interest in two connections.

(a) From the theoretical standpoint it is important to know whether the rate of heat liberation runs parallel with the rate of combination of  $O_2$  (and/or CO) as followed in other ways, such as by the spectroscopic method of Hartridge and Roughton [1923, 1, 2] and the photo-electric method of Millikan [1933]. If the heat effects were found to lag behind or to be divisible into more than one phase in time it would mean that the primary process of combination of  $O_2$  (and/

or CO) with haemoglobin, as revealed by the optical change, must be followed by secondary tautomeric changes after the  $O_2$  (and/or CO) molecule is combined, such as have indeed been found by Roughton [1934] in special cases. Such secondary tautomerisations would be a new feature in the haemoglobin reactions, and would certainly entail a re-formulation of their physico-chemical mechanism.

(b) Failing any discrepancy between the speed of the reaction as followed thermally on the one hand, and optically on the other, the thermal method would provide a valuable alternative means of measuring the rate of the reactions, especially in haemoglobin solutions of high concentration and in suspensions of intact red cells. In the latter, especially, the optical method may be rather inaccurate, on account of the uncertainty due to the scattering of light by the walls of the red cells and of the irregular paths which the light must take through the biconcave shaped cells.

In the present paper comparisons are given of (i) the heat of combination of 1 mol.  $O_2$  with haemoglobin by the usual slow method [Roughton, 1935] and by the rapid thermal method of Part I (ii) the rate of combination of CO with haemoglobin by the optical method and by the rapid thermal method. Preliminary observations are also given of the rate of uptake of  $O_2$  and of CO by suspensions of intact red cells, and in conclusion the further scope of the method, particularly in regard to the kinetics of the reactions of  $CO_2$  in whole blood is pointed out.

## METHODS.

### *Preparation of solutions.*

*Reduced haemoglobin solutions.* Prepared from ox blood containing 1% boric acid and stored at  $+0.5^\circ$ . The blood was reduced by shaking in an evacuated vessel for about 30 min. at about  $40^\circ$  with intervals during which small quantities of purified nitrogen were introduced and the vessel again evacuated. It was then laked by dilution with eight times its volume of air-free water.

*Reduced corpuscles.* Ox corpuscles were washed once with 1% NaCl and then diluted with NaCl solution to the volume of blood originally used. The suspension was reduced and diluted with air-free 1% NaCl to the same extent as in the preparation of reduced Hb solution.

*Oxygen, nitrogen and carbon monoxide.* Cylinder oxygen was used throughout; cylinder nitrogen needed purification when used in the preparation of reduced haemoglobin, and for this purpose it was shaken with alkaline  $Na_2S_2O_4$  containing Na anthraquinone- $\beta$ -sulphonate and stored at increased pressure in a stoneware bottle. Carbon monoxide was prepared from sodium formate and commercial sulphuric acid and stored over alkaline sodium hydrosulphite under pressure. Special precautions—thorough washing out of all leads immediately after the preparation—were needed in order to remove all traces of formic acid from the gas.

### *Determination of rapid heat and time course of its production.*

The general procedure has already been described in some detail in Part I, but certain points peculiar to experiments with haemoglobin require special mention.

4 litres of the reduced haemoglobin solution or corpuscle suspension, stored under nitrogen at a slight positive pressure, were transferred to the evacuated bottle *L*, after all leads had been duly washed out with nitrogen. Similarly 4 litres of water equilibrated with  $O_2$  or CO at atmospheric pressure were transferred to bottle *R* and kept under a slightly increased pressure of  $O_2$  or CO.

After all temperature adjustments had been made, the experiment could proceed exactly as described in Part I, measurements with the differential thermocouple usually preceding those with the absolute couple, in cases where a gradient was expected; in this way the absolute couple could be used under the most favourable conditions.

Samples of effluent were taken in an evacuated tonometer while *L* and *R* were both delivering liquid, and the relative delivery of *L* and *R* was determined colorimetrically, by comparing this effluent with an exactly twice diluted sample from *L*.

The  $O_2$  or CO content of fluid *R*, and the haemoglobin content of fluid *L* were both determined with the Van Slyke-Neill apparatus at the end of the experiment.

The rise of temperature due to the reaction was usually about  $0.005^\circ$ , and in good experiments, could be determined to within  $\pm 0.0002^\circ$ . This corresponds to an experimental error of about 250 calories in the heat of combination of 1 mol  $O_2$  with Hb.

#### *Determination of slow heat.*

The method was in most respects similar to that described by Roughton [1935]: the heat insulation of the thermos flasks was, however, improved by enclosing the flasks completely in a copper jacket through which thermostat water was circulated by means of a rotary pump. With this arrangement the change in temperature of the water during circulation, when the contents of the flasks had sufficiently equilibrated, was less than  $0.01^\circ$ . Temperature adjustment of the thermos flasks to that of the circulating water was made by short periods of electric heating, the internal circulation described by Roughton being dispensed with. The difference in temperature between the contents of the flasks and the circulating water was determined by a second thermocouple.

An additional improvement consisted of the use of ordinary ground-glass syringes for gas reservoirs, a change which made it possible to introduce the  $O_2$  or CO into the thermos flasks without stopping the shaker: one syringe was filled with  $O_2$  (or CO) and the other with  $N_2$ , and at the appropriate instant the contents of both syringes were delivered simultaneously into the respective flasks. In this way, any extraneous heat effects due to compression of gas, water vapour *etc.* are exactly balanced. The entire process of introducing the gas only took about 10 sec.

In good experiments, the possible error in the heat determination by this method is of the order 500–1000 calories per mol  $O_2$  combining with Hb.

#### EXPERIMENTAL RESULTS.

##### *(1) Slow and rapid heats of reaction of $O_2$ with haemoglobin.*

Our first concern was to ascertain whether a temperature gradient could be detected in the observation tube, or whether, as we anticipated from previous work with the optical methods, the reaction would prove to be too rapid for such a gradient to be observed. We found as expected, that at least 98 % of the total temperature rise in the observation tube was complete by the time fluid had travelled 2 cm. from the mixing chamber, *i.e.* in 0.008 sec. The process is thus too rapid for its time course to be followed by the present apparatus, nor would it be of any use to reduce the rate by lowering the  $[O_2]$  in fluid *R*, for this would also make the resultant temperature rise too small to be accurately measured.

We next proceeded to see whether the observed temperature rise, which remained constant during the time required for the liquid to traverse the remainder

of the capillary part of the observation tube, would also remain constant for a further relatively long period, or whether, as seemed possible for the reasons already indicated, there would occur slow secondary processes accompanied by an absorption or evolution of heat. For this purpose the thermojunction was placed in the wide part of the observation tube and deflections were read in the following order: fluid from bottle *R* was run for 20 sec., suddenly turned off, and the galvanometer readings taken at 10 sec. intervals. Then similar drift readings were taken after *R* and *L* had been running together for 20 sec., and again after fluid from *L* alone had been running. In this way drift readings were obtained for successive 10 sec. periods after the completion of the reaction, and any secondary heat production or absorption would have shown itself by a difference between the mean rate of drift of *R* and *L* running separately and that of *B* (*R* and *L* running together). Table IV makes this procedure clearer, and Table V summarises the results of all experiments of this kind (5 in number) which were made, the figures given representing the mean apparent "delayed" temperature change (in mm. galvanometer deflection) for successive 10 sec. periods after mixing. It is clear that although the figures indicate without exception a slight absorption of heat during the first 40 sec. and a slight extra heat production during the subsequent 40 sec., the individual changes are well within experimental error and can be safely disregarded.

Table IV. *Temperature drift in stationary fluids in observation tube.*

Exp. of February 5th, 1935. Hb + O<sub>2</sub>.

As a final test of the correctness of these results, and a general test of the reliability of the method for absolute thermochemical measurement, the heat of reaction of dissolved O<sub>2</sub> and Hb deduced from the steady temperature rise found in the observation capillary was compared, in a series of experiments, with the heat of reaction of similar Hb solutions, prepared from the same sample of blood

and subjected to the same experimental treatment, with gaseous oxygen, the heat being measured by the usual slow calorimetric method. If the foregoing results were reliable, and if the methods were quantitatively satisfactory, the two methods of measurement should have given identical results. Table VI includes all the tests of this kind, which have so far been carried out.

Three of the experiments were, on technical grounds, known to be imperfect, and are therefore bracketed in Table VI. The remaining five, however, show agreement within experimental error, both at alkaline and at neutral reaction and in presence or absence of 1 % boric acid.

Table VI. *Summary of slow and rapid heats of reactions of 1 mol O<sub>2</sub> with Hb.*

Date	$p_{\text{H}}$ and condition of blood	Slow	Rapid
13 March } 22 Feb. }	1% boric blood of 20 Feb. stored at 0°	6500	7300
14 March } 15 Feb. }	1% boric blood of 18 Feb. stored at 0°	(7100)	(7700)
14 March } 20 Feb. }	1% boric blood of 18 Feb. stored at 0°	(10100)	6300
20 March } 22 March }	1% boric blood of 13 March stored at 0°	(7500)	6300
25 March } 26 March }	Blood of 19 March without H <sub>3</sub> BO <sub>3</sub> . Stored— 10°	7700	6300
27 March } 28 March }	1% H <sub>3</sub> BO <sub>3</sub> blood of 26 March. Stored at 0°	6000	6300
2 April	1% H <sub>3</sub> BO <sub>3</sub> blood of 1 April. Alkaline ( $p_{\text{H}}$ ca. 9.5)	7100	6800
3 April	1% H <sub>3</sub> BO <sub>3</sub> blood of 1 April. Neutral	4700	5100

In the rapid experiments the thermo-couple was at 5 cm. from the mixing chamber throughout. The heat values in both columns refer to the reaction of O<sub>2</sub> in solution with haemoglobin in solution.

The values shown in Table VI are apparently much lower than those given by Roughton [1935]. Most of the difference is due to the fact that Roughton's results by the slow method are given for the reaction O<sub>2</sub> (in gas phase) + Hb → O<sub>2</sub>Hb, whilst those in Table VI are for O<sub>2</sub> (in solution) + Hb → O<sub>2</sub>Hb and must therefore be lower than the former by an amount equal to the heat of solution of O<sub>2</sub> at 17°, viz. 2800 calories. It is possible, in addition, that the eight-fold dilution of the blood used in the present paper causes a slight lowering in the heat of reaction.

(2) *Rate of reaction of CO and haemoglobin by thermal and optical methods.*

The first experiment with CO water showed that, in agreement with the optical results of Roughton [1934] the CO + Hb → COHb reaction occurs much more slowly than the O<sub>2</sub> + Hb → O<sub>2</sub>Hb reaction; at such a rate, indeed, that the detailed course of heat production could be very easily followed by observations with the differential thermocouple placed in various positions along the observation tube. The curves so obtained at first showed signs of a small absorption of heat in the upper part of the tube, but further investigation with pure water in each bottle showed that this effect was due to the blank correction already referred to in Part I (p. 2627). The curves could then be converted into % COHb-time curves by:

(i) Application of the blank corrections (*v.* Tables I and II).

(ii) Determination of the absolute temperature rise at any given point in the observation tube by means of the absolute thermocouple.

(iii) The necessary small corrections for differences in rate of flow of liquid where the position of the differential couple was varied or where the absolute couple was in the tube.

(iv) A knowledge of the total CO capacity of the haemoglobin solution.

These final curves were of the usual type, approaching asymptotically an end-point and having a half reaction time,  $\tau$ , of about 0.01 sec.; the results of a typical experiment are given in Fig. 2. Six experiments in all were performed, with such consistent results that only one need be shown. The end-point in each case corresponded to a heat of reaction of about 8000 cal.

Fig. 2. Rate of  $\text{CO} + \text{Hb} \rightarrow \text{COHb}$  by 2 separate methods:  $L = 1.4 \text{ mM Hb}$  (borated blood 1 in 4).  $R = 1.0 \text{ mM CO}$ ; temperature  $= 20^\circ$ .

Fig. 3. Rate of uptake of  $\text{O}_2$  and  $\text{CO}$  by red blood corpuscle suspensions.

As a final check on these curves, they were compared with those obtained on the same sample of blood by the optical method, for which we have to thank Dr G. A. Millikan. Fig. 2, depicting the results of a typical thermal experiment, likewise gives the points obtained in the same material by the optical method. The agreement is excellent, so that the conclusions drawn in the case of the

O<sub>2</sub>-Hb reaction also apply here: there is no evidence for the existence of secondary heat processes, and no reason to suppose that the heat production does not proceed precisely in step with the optical change.

(3) *Comparison of rate of reaction of O<sub>2</sub> and CO with (a) Hb in solution and (b) Hb in intact corpuscles.*

Whereas in the case of the reaction of O<sub>2</sub> with Hb in solution no temperature gradient could be detected in the observation tube, it was easy to show that with corpuscle suspensions containing the same average concentration of haemoglobin, a gradient could be consistently observed, so that the effective half-reaction time was increased from < 0.002 sec. to about 0.007 sec. In the case of the slower reaction with CO, the diffusion effect was naturally less significant but was nevertheless unmistakable, the time of half reaction being increased from 0.010 to 0.016 sec. at 20.5°. Some preliminary experiments are shown in Fig. 3.

DISCUSSION.

It is clear that the slow and rapid heats of these haemoglobin reactions are identical within the limits of experimental error. This is evidence against the existence of any secondary reactions, at any rate of marked heat content.

The hypothesis of secondary changes, following the primary combination of O<sub>2</sub> or CO with haemoglobin, is not supported by the results of a direct search for secondary heat effects following the primary evolution of heat: in the case of the rapid O<sub>2</sub> + Hb → O<sub>2</sub>Hb reaction it is shown that the total heat is evolved within 0.008 sec. or less of mixing, and that the mixed fluids show no further temperature change over a period of 80 sec. In the case of the CO + Hb → COHb reaction, the evolution of heat followed the same course as the optical change, and thus again the search for secondary changes gave negative results. The excellent agreement between the thermal and optical data, however, suggests that results, by the thermal method, of experiments, in which optical data are either unobtainable or suspected to be inaccurate, can be accepted with confidence.

An example is provided by the preliminary experiments on suspensions of intact red blood corpuscle suspensions, where reliable optical data are difficult to obtain, on account of the optical heterogeneity of the medium and the consequent scattering of light. The experiments demonstrate quantitatively the importance of diffusion, a factor which had on theoretical grounds been shown by Roughton [1932] to be of importance in regulating the rate of uptake of dissolved gases by the red blood corpuscles. They suggest that further experiments on the same lines might provide the quantitative data necessary for a fuller knowledge of the diffusion coefficients of O<sub>2</sub> and CO in the contents of the corpuscles and in the membrane surrounding them. In principle it might be objected that the time relations in thermal records of reactions proceeding within the red blood corpuscles are distorted by the slowness of thermal conduction from the corpuscle to its surroundings: fortunately it is easy to show that in the times at present under consideration the error thus introduced is negligible. Assuming the corpuscle to be a plane sheet of thickness 1.4 μ and thermal conductivity = that of water = 1.4 × 10<sup>-3</sup>, it is found (by calculations similar to those of Roughton [1932] on diffusion of O<sub>2</sub> and CO within the corpuscle) that the transfer of heat from the inside of the corpuscles to the surroundings would be 98% complete within a period of 0.0003 sec., whereas the half-reaction times in these experiments are of the order of 0.01 sec., i.e. 30 times greater.

*Further scope of the method in blood reactions.* The method is now being applied to the kinetics of the  $\text{CO}_2$  reactions, which differ from those of  $\text{O}_2$  in blood in not being accompanied by colour changes, which can conveniently be followed by optical methods. Already it has been possible to measure the heat of the separate reactions  $\text{H}^+ + \text{HCO}_3^- \rightarrow \text{H}_2\text{CO}_3$ , and  $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$ , the usual methods of calorimetry having hitherto only been able to give the sum of the heats of these two reactions, without any indication as to their individual values. Having obtained this basal information it is hoped now to proceed to the thermal study of the kinetics of the  $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$  reaction in the red blood corpuscle, which contains large amounts of the catalyst for this reaction—carbonic anhydrase. The thermal method also appears to be the most promising one for determining the rate of carbamino-combination of  $\text{CO}_2$  with haemoglobin—a process which has recently leapt into importance in the physiological transport of  $\text{CO}_2$  by the blood. There is thus a large field awaiting the application of the method in blood kinetics and possibly in other biochemical problems also.

#### SUMMARY.

1. In Roughton's method for recording the time course of the heat effects in rapid chemical changes, the two reagents are driven by separate leads into a mixing chamber and thence into an observation tube: the temperature of the running fluid at various points of the latter is measured thermoelectrically to an accuracy of  $\pm 0.001^\circ$ . The present method was required, and was designed for, the study of reactions in which the total temperature change does not exceed  $0.005$ – $0.01^\circ$  and hence necessitates, as regards the temperature measurement, a 5- to 10-fold greater precision than its predecessor. This has been obtained in part by special attention to the dimensions and lay-out of the apparatus, but in the main by immersing the whole apparatus in a water thermostat, the leads, mixing chamber and observation tube being, however, separated from the water by air jackets. These improvements have made it feasible to use a galvanometer of 7 times greater sensitivity per mm. deflection than heretofore.

2. Tests show that blank effects and/or errors of non thermochemical origin are of the order of  $0.0004$ – $0.0008^\circ$ , and that by following exactly the technique described in the text:

(a) The "absolute" temperature difference between one junction in the running fluid and the other (the "cold" one) at a standard temperature outside can be measured to an accuracy of  $\pm 0.0002^\circ$  on the average.

(b) The difference in temperature between two points in the observation tube, through which the mixed fluid is running, can be measured to an accuracy of  $\pm 0.00004^\circ$  on the average. The method is thus competent to follow, to within 1–2%, the time course of heat effects, over a period of  $0.001$  sec., in which the total temperature change does not exceed  $0.01^\circ$ .

3. The method has been applied to the study of the rapid thermochemistry of the reactions of haemoglobin with oxygen and carbon monoxide. It is found that:

(a) In the case of the  $\text{O}_2 + \text{Hb} \rightarrow \text{O}_2\text{Hb}$  reaction, the heat liberated within  $0.008$  sec., does not differ within the limits of error from the total heat liberated in 10–15 min., as measured by the usual slow methods of calorimetry; nor is there any evidence of delayed heat effects during the intermediate period between these two extremes.

(b) The rate of the  $\text{CO} + \text{Hb} \rightarrow \text{COHb}$  reaction, as measured by the thermal method, agrees very closely with the rate given by Millikan's photo-electric

method. These results not only confirm the validity of the rapid thermal method, but also show that the primary combination of  $O_2$  and/or CO with haemoglobin is not followed by any secondary reactions, at any rate of appreciable heat content, and that the heat changes do keep pace exactly with the optical changes in the reaction. The thermal method can thus be used with confidence for rapid reactions in which optical methods are inapplicable or less suitable, such as the uptake of  $O_2$  and CO by haemoglobin in intact red cell suspensions, of which some preliminary instances are given.

4. The further scope of the method, particularly in the study of the kinetics of the  $CO_2$  reactions in whole blood, is pointed out. On the technical side the main desideratum is no longer an increase in accuracy, but rather a diminution in the volume of reagents required for each experiment, since this at present amounts to about 4 litres.

Our thanks are due both to the laboratory mechanic, Mr W. L. Hall, and to our technical assistant, Mr A. Secker, for much help in the detailed design of the apparatus and the carrying out of the experiments.

## OBITUARY NOTICE.

RONALD SYDNEY MORGAN.

(1904-1935.)

RONALD SYDNEY MORGAN was born in London in 1904. He was educated at the City of London School and the Royal College of Science and Technology, South Kensington, where, after obtaining a First Class Honours degree in Chemistry, he carried out research under a College grant. In 1926 he was appointed principal assistant to the head of the Food Research Section of Messrs Lever Bros. Ltd. at Port Sunlight; four years later he was given complete charge of the Animal Nutrition Laboratory which was re-opened at Spittal Old Hall and he was largely responsible for the extension and re-organisation of that department. Morgan took full advantage of the exceptional opportunities thus afforded. At the time of his appointment there was much work to be done with regard to methods of manufacture of fat-soluble vitamin concentrates and his researches concerning the technique of the preparation and assay of vitamins A and D have provided valuable contributions to the service of both Industry and Science. His work at Port Sunlight was held in very high esteem both by his principals and colleagues and he was not only admired for his scientific ability and powers of achievement but was recognised as a man who had an abundant capacity for friendship and service to all with whom he came in contact. Those who worked with him believed that he had a brilliant future before him and his sudden and tragic death on the 6th October last has cut off a life which was full of promise. He leaves a widow and two children.

# CCCXII. THE NATURE OF THE INJURY TO THE CALCIFYING MECHANISM IN RICKETS DUE TO STRONTIUM.

By ALBERT EDWARD SOBEL, JULIUS COHEN  
AND BENJAMIN KRAMER.

*From the Pediatric Research Laboratory of the Jewish Hospital  
of Brooklyn, N.Y., U.S.A.*

*(Received September 6th, 1935.)*

WHEN young rats are fed on diets containing strontium carbonate they become rachitic. The bones of these animals are characterised by a markedly diminished calcifying mechanism [Sobel *et al.* 1934]. At present, the nature of the alteration in the bone cell causing this variation is quite obscure. In fact, the entire problem of the factors operating locally in the bone cell is still unsolved. Whilst there are a number of theories as to what constitutes the "local factor", the bone "phosphatase mechanism" is the only one supported by satisfactory experimental evidence [Robison, 1932; Robison and Rosenheim, 1934; Niven and Robison, 1934; Fell and Robison, 1934]. Even this enzyme is known not to be the only factor involved as was confirmed in our studies of strontium rickets [Sobel *et al.*, 1935]. A further study of strontium rickets is therefore of importance because of the information that may be revealed regarding the factors responsible for calcification at the site of deposition. The present experiments seem to point to a "competitive retardation" of  $\text{Sr}^{++}$  upon the action of a constituent of the bone cell whose concentration is a factor in calcification. This experimental evidence is discussed below.

Referring to the results in our recent paper [Sobel *et al.*, 1934] the question arose whether or not the destruction of the calcifying mechanism is complete in strontium rickets. This was studied by using artificial serum solutions having a  $\text{Ca} \times \text{P}$  product higher than 60 for observations of *in vitro* calcification in the bones. In this manner it was shown that at a  $\text{Ca} \times \text{P}$  product of 90 the amount of *in vitro* calcification corresponds to that obtained at a  $\text{Ca} \times \text{P}$  product of 40 in the control group. This observation suggests that besides the concentration of  $\text{Ca}^{++}$  and  $\text{PO}_4^{=}$  the concentration of at least one other factor is involved in bone formation. In strontium rickets this factor appears to be reduced and therefore the  $[\text{Ca}^{++}]$  and  $[\text{PO}_4^{=}]$  must be increased to compensate.

However, another possible explanation suggested itself. Strontium ions might remove the available phosphate ions by forming an unionised complex. This has been regarded as the most likely mechanism responsible for the inhibitory effects of magnesium ions [Shelling *et al.*, 1928] and of protein [Shipley *et al.*, 1926] upon calcification *in vitro*. To determine whether or not this is so a study of the effect of  $\text{Sr}^{++}$  upon calcification *in vitro* was undertaken. It was first demonstrated that  $\text{Sr}^{++}$  inhibits calcification *in vitro*. This inhibition was then studied quantitatively using bone slices from animals with calcium rickets. The sections were incubated in artificial serum solutions with a  $\text{Ca} \times \text{P}$  product of 60 ( $\text{Ca} = 10 \text{ mg./100 ml.}$ ,  $\text{P} = 6.0 \text{ mg./100 ml.}$ ) and varying amounts of  $\text{Sr}^{++}$ . 2.0–2.5 mg. of  $\text{Sr}^{++}$  in 100 ml. of solution were sufficient completely to

inhibit calcification *in vitro*, although a  $\text{Ca} \times \text{P}$  product of 35 is sufficient in the absence of  $\text{Sr}^{++}$  for *in vitro* deposition. Even if it is assumed that Sr exists as a completely unionised phosphate where the  $\text{Sr}/\text{PO}_4$  ratio is similar to that in  $\text{SrHPO}_4$ , 2.5 mg. of Sr would remove only 0.88 mg. of P which would still leave an effective  $\text{Ca} \times \text{P}$  product of 51 ( $10 \times 5.1$ ), quite ample for *in vitro* calcification. Thus, it may be seen that this inhibitory effect of  $\text{Sr}^{++}$  may be explained by assuming that Sr acts directly upon a constituent of the bone cell. In view of the fact that the *in vitro* deposition of Sr has been demonstrated [Robison and Rosenheim, 1934] a competitive behaviour between  $\text{Sr}^{++}$  and  $\text{Ca}^{++}$  for a factor residing in the bone may be readily imagined. Such an explanation also harmonises the inhibitory effect of  $\text{Mg}^{++}$  upon *in vitro* calcification with the reported deposition of Mg *in vitro* [Robison and Rosenheim, 1934].

Whilst the above explanation is very attractive, there may be two other explanations for the interference of  $\text{Sr}^{++}$  with calcification within the bone cell. (1) Formation of a soluble Sr-Ca phosphate complex. This would explain the phenomenon on a purely physico-chemical basis. (2) Impairment of a vital function of the bone cell due to the toxic action of Sr. In the first case normal calcification should be re-established as soon as the  $\text{Sr}^{++}$  is removed. Since the diffusion of  $\text{Sr}^{++}$  should be rapid in a solution free from Sr, the restoration of the calcifying mechanism should take place readily. In the second case the damage should be practically irreversible, since there is no reason to believe that vital function will be restored unless the damaged tissue is replaced. If the inhibition is caused by a competitive behaviour between Sr and Ca as outlined in the previous paragraph, then the damage to the calcifying mechanism should be reversible. The rate of such a change would depend upon the velocity at which the Sr complex breaks down. This process would in all likelihood be slower than mere diffusion as postulated in the first possibility.

The question of the reversibility of the injury to the calcifying mechanism in strontium rickets was therefore studied both *in vivo* and *in vitro* in experiments in which the strontium-treated bone cells were subsequently bathed in fluids that did not contain  $\text{Sr}^{++}$ .

To demonstrate this reversibility *in vivo*, animals which had at first developed strontium rickets were transferred to the calcium rachitic diet and daily observations were made of *in vitro* calcification. At the end of 3 days the *in vitro* response was similar to that of the control group. Thus, a restoration of the calcifying mechanism was readily observed by *in vivo* methods. It was of interest to note that after 2 weeks on the calcium rachitic diet the average weight of the animals attained that of the controls. Moreover, *in vivo* healing could be readily observed in 7 days if vitamin D accompanied the calcium rachitic diet.

To determine whether the restoration of the calcifying mechanism occurred *in vitro*, slices of bones from animals with strontium rickets were incubated for 72 hours instead of the customary 20 hours at a  $\text{Ca} \times \text{P}$  product of 60. After 72 hours there was a marked increase in the amount of deposition in the strontium group when compared with the degree of calcification in 20 hours. These results are remarkable since it is known that the calcifying mechanism in the usual type of rachitic section disappears in about 20–24 hours when immersed in an artificial serum solution having too low a  $\text{Ca} \times \text{P}$  product for new deposition [Robison and Rosenheim, 1934]. This loss of the calcifying mechanism was confirmed by the present authors. Moreover, the control sections in the above experiment showed maximum amount of *in vitro* calcification in about 20 to 24 hours. Apparently, in the strontium group there is a gradual restoration of the calcifying mechanism whilst the reverse process takes place

in the control group during the same time. According to the above conception, it can be postulated that Sr in some manner prevents destruction of the calcifying mechanism. To explain this, one must assume the existence of a stable Sr complex with the same factor whose loss is a reason for the gradual destruction of the calcifying mechanism in the control group. If this complex undergoes the slightest dissociation then ultimately there will be an almost complete release of this factor in the free state, since the Sr will continue to diffuse out of the cell in a medium in which the concentration of  $\text{Sr}^{++}$  is comparatively low. In such fashion the gradual increase of calcification can be explained. This explanation would be in harmony with the theory of a competitive action of Sr with Ca for a factor whose concentration plays a part in calcification.

It can readily be seen that the other two explanations offered for the interference of strontium with the calcifying mechanism cannot hold. If the injury were a purely physico-chemical mechanism, then a gradual decrease in calcification should take place in the strontium group during a prolonged period of time just as it does in the control group, since it is likely that Sr could not preserve the bone-forming mechanism unless it were in combination with it. On the other hand, if the injury were inflicted upon the vital action of the cell then simple removal of Sr would not cause a restoration of the vitality of the cell in a purely inorganic solution which can hardly allow for the building up of organic tissue.

#### EXPERIMENTAL.

Albino rats raised in our laboratory from an original Wistar strain were used. The mothers were kept on the stock diet of Bills *et al.* [1931]. The young were ordinarily weaned at 21 days of age at which time they were placed on the stock diet. At 3 to 4 weeks of age administration of the experimental diets was begun. These were modifications of the Steenbock-Black [1925] rickets-producing diet which consisted of a basal regimen with addition of Ca or Sr as follows:

	Basal diet 1 $B_1$	Basal diet 2 $B_2$
Cornmeal (Quaker Oats)	71 g.	70 g.
Wheat gluten	20 g.	16 g.
Brewer's yeast (Mead's)	5 g.	10 g.
NaCl	1 g.	1 g.
	P = 0.23 g. = 7.4 mg. mol.	P = 0.15 g. = 4.8 mg. mol.
Ca rachitic diet—Basal diet 97 g. + 3 g. of $\text{CaCO}_3$ Ca = 1.2% = 30.0 mg. mol./100 g.		
Sr rachitic diet—Basal diet 97 g. + 3 g. $\text{SrCO}_3$ Sr = 1.7% = 19.4 mg. mol./100 g.		

In the first experiments diet  $B_1$  was used. Later on, when a favourable effect of diet  $B_2$  was noted in the growth of the calcium rachitic group, this diet was used in producing strontium rickets. In the latter case, both the growth curve and the *in vitro* response of the bones were similar to those on diet  $B_1$ .

The animals were X-rayed regularly once a week for the duration of the experiment. Plate VI, figs. 1 and 2 are typical roentgenograms of a young rat suffering from rickets due to strontium and of one suffering from rickets due to calcium. It is to be noted that at the border zone of the metaphysis and diaphysis in the tibiae of the strontium-fed animal a double line is present. This double line seems to be characteristic of strontium rickets and persists even 2 weeks after transferring the strontium fed group to the calcium rachitic diet, which is as far as such a change has been followed by the authors. Histologically, the bone

Fig. 1. Roentgenogram of the rear part of a rat suffering from rickets due to strontium.

Fig. 2. Roentgenogram of the rear part of a rat with control rickets.

picture is essentially that described by Shipley *et al.* [1922]. There is persistence of the proliferating cartilage with increased osteoid tissue, the epiphysodiaphyseal junction is irregular and resorption of the bones is checked.

The percentage bone ash in general had a tendency to decrease with prolonged experimental period and increase with the initial age of the experimental animals. The average values for the bone ash percentage of the fat-free femora from the strontium groups varied from 28% to 35% in different experiments after 21 days on the experimental diet. Most of these were between 31 and 34%. There was no significant difference in the bone ash values between the animals on diet B<sub>1</sub> and diet B<sub>2</sub>. In the calcium group the bone ash values of the animals on B<sub>1</sub> diet ranged around 29% whilst those for the B<sub>2</sub> group ranged around 34%.

The amount of growth was negligible in the strontium group during a 3-week period on the diet. During a similar period the weight gain of the calcium group on diet B<sub>1</sub> averaged 15–25 g. and that of those on diet B<sub>2</sub> averaged 40–50 g.

It was also observed that animals which were transferred from a 14-day strontium regimen to a subsequent 14-day calcium diet caught up in weight to those on the calcium diet for 28 days.

At the end of the experimental period the animals were sacrificed and the tibiae were removed for observations of *in vitro* calcification. The technique of Shipley *et al.* [1926] was used, artificial serum solutions having various Ca × P products being employed as media in which slices of the growing ends of the bones were bathed at 37°. After 20 or 72 hours the bones were removed, stained with silver nitrate, cleared and mounted.

Most of the experiments were reproduced 3 to 4 times. For the sake of brevity only typical experiments are described.

*Calcification in vitro of the bones of animals suffering from rickets due to strontium.*

The *in vitro* responses of bones of animals on diets B<sub>1</sub> and B<sub>2</sub> were observed at 14, 21 and 28 days on the experimental diet. Similar results were obtained for these various periods. At a Ca × P product of 10 × 6 the strontium group failed to show calcification.<sup>1</sup> At a Ca × P product of 15 × 6 the degree of *in vitro* calcification was about + to + + + +. This corresponds to the degree of calcification observed in the controls at Ca × P 10 × 4. The control group at Ca × P 15 × 6 showed 4 ( + + + + ) healing. All the above observations were taken after a 20-hour period of incubation.

*The inhibitory effect of Sr<sup>++</sup> upon calcification in vitro.*

Sections of tibiae from animals suffering from rickets due to calcium were incubated in an artificial serum solution with Ca × P 10 × 6 and varying amounts of Sr<sup>++</sup> in the form of SrCl<sub>2</sub>. 2.5 mg. of Sr<sup>++</sup> in 100 ml. of solution were sufficient completely to inhibit calcification in all cases. 2.0 mg. of Sr<sup>++</sup> were sufficient to inhibit in a number of cases.

<sup>1</sup> The degree of calcification is indicated as follows: + trace; + + broken thin line; + + + almost complete thin line across the provisional zone; + + + + complete thin line across the provisional zone; 2 ( + + + + ) heavy line across the provisional zone including the primary tongues of cartilage; 3 ( + + + + ) heavy line across the provisional zone including the primary and secondary tongues of cartilage; 4 ( + + + + ) practically complete calcification of the metaphysis.

*The reversibility of the injury to the calcifying mechanism in vivo.*

Observations were made of the *in vitro* response of the bones of animals which were maintained for 2 weeks on strontium diet B<sub>1</sub> followed by 2 weeks on calcium diet B<sub>1</sub>. Identical observations were also made on a control group of animals kept on calcium diet B<sub>1</sub> for 4 weeks. The results were similar in both groups. At Ca × P 10 × 6 the response was 2 (++++ ) and at Ca × P 15 × 6 it was 4 (++++ ). Another group of animals was given daily doses of 33 Steenbock units of viosterol after they were transferred to the calcium diet from the strontium diet. After 7 days on the viosterol and calcium diet regimen, marked healing was observed *in vivo* in these animals.

In the next experiments animals on the strontium diet for 3 weeks were transferred to the calcium diet and daily observations were made of the *in vitro* response of the tibiae at Ca × P 10 × 6 as compared with controls. After 3 days on the diet the rats in the strontium group showed an *in vitro* response similar to that of controls.

*The reversibility of the injury to the calcifying mechanism in vitro.*

Slices of bones from animals with strontium rickets and with calcium rickets were incubated in artificial serum solutions having Ca × P 10 × 6. Observations were made at 20 and at 72 hours. At the end of 20 hours the strontium group showed either no calcification or only the faintest traces of it. In contrast to these findings the control group showed 2 (++++ ) to 3 (++++ ) healing. After 72 hours the strontium group averaged +++ to ++++ healing whilst the control group showed about the same amount of calcification in 72 hours as in 20 hours.

*The loss of calcifying mechanism in vitro.*

To confirm the experiments of Robison and Rosenheim [1934] sections of bones from the calcium rachitic group were incubated for 4, 7 and 24 hours in an artificial serum solution of Ca × P 10 × 2 which is too low a product to cause *in vitro* calcification. After this preliminary immersion they were placed in solutions with Ca × P 10 × 6 and 15 × 6 for 24 hours. No healing was observed after the 24-hour immersion. After 7 hours there was practically no response at Ca × P 60 whilst at 90 the amount of response was + to +++++, which corresponds to that usually obtained at Ca × P 40. After 4 hours of immersion there was a slight response at Ca × P 10 × 6 corresponding to that obtained at Ca × P 10 × 3.5, whilst at Ca × P 10 × 9 the response corresponded to that usually obtained at Ca × P 10 × 5.0 that is +++++ to 2 (++++ ).

## SUMMARY.

1. Comparative observations of *in vitro* calcification of bones obtained from rats with strontium and with calcium rickets were made. It was found that there was a marked diminution, but not a complete destruction, of the calcifying power of the bones of animals suffering from strontium rickets.

2. The injury to the calcifying mechanism, in the bones of animals suffering from rickets due to Sr, was shown to be reversible both *in vivo* and *in vitro*. This was accomplished by bathing the bone cells in fluids which were free of strontium.

3. The inhibitory effect of  $\text{Sr}^{++}$  upon calcification *in vitro* was determined. A high degree of inhibition was obtained, which favours the explanation that  $\text{Sr}^{++}$  has a direct effect upon some constituent of the bone cell.

4. It is suggested that Sr combines with a factor whose concentration plays a part in calcification and thereby reduces the rate of bone formation.

# CCCXIII. PHOSPHATASE ACTIVITY AND CALCIFICATION IN STRONTIUM RICKETS.

BY ALBERT EDWARD SOBEL, JULIUS COHEN  
AND BENJAMIN KRAMER.

*From the Pediatric Research Laboratory of the Jewish Hospital  
of Brooklyn, N.Y., U.S.A.*

*(Received September 6th, 1935.)*

IN view of the great importance attached to the rôle of bone phosphatase in the intimate mechanism of bone formation [Robison, 1932; Kay, 1932; Robison and Rosenheim, 1934; Niven and Robison, 1934; Fell and Robison, 1934] investigations were undertaken to determine whether the remarkably reduced calcifying power of the endochondral cartilage in strontium rickets [Sobel *et al.*, 1934] is associated with a decreased activity of this enzyme. Either a retarding effect of  $\text{Sr}^{++}$  on the activity of bone phosphatase, or the interference of strontium with the formation or retention of this enzyme in the bone or cartilage cell or both may cause such a change.

With these considerations in mind the effect of various concentrations of  $\text{Sr}^{++}$  on the activity of bone phosphatase was determined (as measured by the amount of sodium glycerophosphate hydrolysed per hour); no significant change in the activity of the enzyme was observed.

This negative result however did not rule out the possibility of a decreased phosphatase content in the bone cells of animals suffering from strontium rickets when compared with the phosphatase content of the bone cells in calcium rickets. Consequently, the phosphatase content in similar anatomical portions of the tibiae of animals suffering from strontium rickets was compared with that of corresponding portions removed from animals with calcium rickets. In addition, these enzyme values were compared with those of bones removed from animals which had previously developed strontium rickets and which were then changed to the calcium rachitic diet and maintained on this diet until the *in vitro* calcifying property of the bone cartilage was restored.

The results of these investigations have shown no significant differences in the phosphatase contents of the tibiae of the various groups of animals, although there was marked difference between the *in vitro* calcifying powers of the tibiae in the same groups. Incubating the tibiae of the animals suffering from rickets due to strontium in artificial serum solutions with a  $\text{Ca} \times \text{P}$  product of 60 for 22 hours failed to show new calcification. In contrast, the control rachitic group showed ample new calcification under identical conditions. The strontium group which was transferred to the calcium rachitic diet showed deposition similar to that observed in the control group.

It is obvious from our results that some factor other than phosphatase activity is altered in the bone cells of animals suffering from strontium rickets. Before the nature of this injury can be understood it will be necessary to understand the process of calcification in the matrix of the bone cartilage cell. It is hoped that further investigations, which are in progress, will throw additional light upon the subject.

*Determination of phosphatase activity.*

The tibiae were carefully excised. The epiphyseal portion of the bone just above the junction of the fibula was sliced into very small thin sections which were placed in small bottles containing 10 ml. of water saturated with chloroform. After 12 days the bottles were vigorously shaken in a machine for 8–12 hours. The extract was then filtered through a No. 42 Whatman filter-paper. At this stage, following the technique of Bodansky [1933], 10 ml. of substrate were measured into a test-tube 18 × 200 mm., warmed to 37° and then treated with 1 ml. of the filtered bone extract. The contents were mixed by a single inversion and the tube placed in a water-bath at 37°. After exactly 1 hour the test-tubes were transferred to an ice-bath and 9 ml. of 18% trichloroacetic acid added. The contents were then mixed and filtered through two Whatman No. 42 filter papers. 2.5 ml. of this filtrate were used for the determination of inorganic phosphate following the technique of Fiske and Subbarow [1925] except that the amounts of reagents used and the final volume were halved. The inorganic phosphate content of the bone extract was determined by adding 2 ml. of 20% trichloroacetic acid to 3 ml. of the extract and using 2.5 ml. of the filtrate for the colorimetric determination as outlined above.

The phosphatase activity was expressed as mg. P liberated as inorganic phosphate by each bone in 1 hour.

The technique used for the determination of the phosphatase activity of these bones was acquired after considerable preliminary investigations to determine the best conditions for the extraction of the enzyme. The method finally adopted is such that in our hands there was no measurable enzymic activity left in the residual bone. The greatest source of error lies in excision and subsequent slicing of the tibia; therefore special precautions were taken in both cases. The tibia was excised in such a manner as to exclude any part of the fibular epiphysis, yet completely to include the tibial epiphysis. The slicing was carried out with sharp Bard-Parker blades, after which the blades were washed by dipping them into the chloroformed water used for the extraction of the particular bone.

The  $p_H$  of the substrate was 9.5 with our reagents when prepared according to Bodansky [1933]. When  $p_H$  8.8 was desired the adjustment was made by adding hydrochloric acid. No change of  $p_H$  was observed after the hydrolysis; this is to be expected because only a small fraction of the substrate is hydrolysed.

Measurements of phosphatase activity were made at  $p_H$  9.5 and 8.8. Parallel determinations at both reactions were carried out in some cases on aliquot samples of the same bone extract. The mean ratios<sup>1</sup> of 14 parallel determinations are presented in Table I.

Table I. *Comparative phosphatase activities at  $p_H$  8.8 and 9.5.*

No. of bones 14.	
Relative bone phosphatase activity	$\frac{p_H \text{ 8.8}}{p_H \text{ 9.5}} = 0.640 \pm 0.0048$
“ “ “	$\frac{p_H \text{ 9.5}}{p_H \text{ 8.8}} = 1.56 \pm 0.013$

The results of a series of observations all through this paper are expressed as the mean value  $\pm$  probable error of the mean.

*The effect of strontium ions on the activity of bone phosphatase.*

To 10 ml. of substrate ( $p_H$  8.8) various amounts of  $Sr^{++}$  in the form of  $SrCl_2$  were added. The  $p_H$  was adjusted to 8.8 by suitable addition of alkali. The final volume was made up to 12 ml., to which 1 ml. of bone extract was added. The relative phosphatase activities are shown in Table II.

Table II. *Relative phosphatase activities in the presence of various amounts of  $Sr^{++}$ .*

mg. of $Sr^{++}$ in 100 ml. of hydrolysis mixture	0.0	0.2	1.0	4.0	20.0	80.0
Relative phosphatase activity	1.00	0.99	0.97	0.98	1.01	1.11

It can be readily seen from the table that much larger amounts of strontium than are likely to occur physiologically do not interfere with the activity of the enzyme.

*Comparative bone phosphatase studies.*

Albino rats raised in our laboratory from an original Wistar strain were used. The mothers were kept on the stock diet of Bills *et al.* [1931]. The young were ordinarily weaned at 21 days at which time they were placed on the stock diet. At the age of 23–24 days, this was replaced by the experimental diet which was a modified Steenbock-Black [1925] rickets-producing diet consisting of a basal regimen with addition of Ca or Sr as follows:

Basal diet: Corn meal 71 parts

Wheat gluten 20 parts

Brewer's yeast (Mead's) 5 parts

NaCl 1 part

Ca rachitic diet: Basal diet 97 parts + 3 parts of  $CaCO_3$

Ca = 1.2% = 30.0 mg. mol./100 g. P = 0.14% = 45 mg. mol./100 g.

Sr rachitic diet: Basal diet, 97 parts + 3 parts of  $SrCO_3$

Sr = 1.7% = 19.4 mg. mol./100 g. P = 0.14% = 45 mg. mol./100 g.

After about 21 days, when the X-ray examination showed evidence of marked rickets, the animals were either sacrificed or transferred to the calcium rachitic diet for 3 to 4 days, and some of the tibiae removed for observations of *in vitro* calcification. The technique of Shipley *et al.* [1926] was used, artificial serum solutions having Ca  $\times$  P product of 60 being employed as media in which slices of the growing ends of the bones were bathed at 37°. After 20 hours the bones were removed, stained with silver nitrate, cleared and mounted. In all cases our previous observations were confirmed. The strontium rachitic animals showed no deposition whilst the calcium rachitic group showed about 2 (++++ ) to 3 (++++ ) healing.<sup>1</sup> Both tibiae of the remaining animals were used for the determination of phosphatase activity using the technique outlined previously. The experiments described below do not include the preliminary investigations which were necessary for the standardisation of the technique.

In the first experiment 25 animals were placed on the calcium diet and 21 on the strontium diet. After 21 days the animals were killed. The tibiae of four animals in each group were employed for the study of *in vitro* calcification. Both

<sup>1</sup> The degree of calcification is indicated as follows: + trace; ++ broken thin line; +++ almost complete thin line across the provisional zone; ++++ complete thin line across the provisional zone; 2 (++++ ) heavy line across the provisional zone including the primary tongues of cartilage; 3 (++++ ) heavy line across the provisional zone including the primary and secondary tongues of cartilage; 4 (++++ ) practically complete calcification of the metaphysis.

tibiae of the remaining animals were removed by the technique described, and used for subsequent determination of phosphatase activity at  $p_H$  of 9.5. The results of the experiment are presented in Table III.

Table III. *Comparative phosphatase activities at  $p_H$  9.5 in the tibiae of animals suffering from strontium and calcium rickets.*

	Ca rickets 21	Sr rickets 17
No. of animals used for phosphatase determinations (two tibiae from each)		
Mean initial weight in g.	36.3 $\pm$ 0.7	45.7 $\pm$ 0.8
Mean final weight in g.	54.9 $\pm$ 1.4	50.6 $\pm$ 1.1
Mean phosphatase activity (mg. P/hour/bone)	2.74 $\pm$ 0.07	2.66 $\pm$ 0.07
Diff.		0.08
$\frac{P.E._{diff}}{Mean \text{ phosphatase activity} \times 100}$		0.099
$\frac{Mean \text{ phosphatase activity} \times 100}{Mean \text{ final weight}}$	5.0	5.25
Calcification <i>in vitro</i> at $Ca \times P = 60$	2 ( + + + + ) 3 ( + + + + )	None

From Table III it will be observed that the amount of *in vitro* deposition is markedly less in each of the strontium-fed groups than in the control group. At a  $Ca \times P$  product of 60 sections of the bones of the strontium-fed groups showed no deposition. In contrast to these findings the tibiae of the control group showed a heavy line involving the primary and secondary tongues of cartilage.

The mean phosphatase activity of the calcium group is 2.74 as compared with 2.66 in the strontium group. The difference of 0.08 is so small that it could not explain the marked differences observed in *in vitro* calcification studies. Furthermore, this difference is not statistically significant (see Table IV). It can therefore be safely concluded that the phosphatase contents of corresponding anatomical portions of bone are the same in both the above groups.

In the second experiment 40 animals were divided into three groups. Group A consisted of 16 animals and received the calcium rachitic diet; group B consisted of 13 animals and received the strontium rachitic diet; group C consisted of 11 animals which had also received the strontium rachitic diet at first. After 21 days 7 animals of Group A and all of Group B were sacrificed. The tibiae of

Table IV. *Comparative phosphatase activities at  $p_H$  8.8 in the tibiae of animals suffering from strontium and calcium rickets.*

	Group A Ca rickets 7	Group B Sr rickets 10	Group C Sr rickets + 4 days of Ca rachitic diet 5
No. of animals used for phosphatase determinations (two tibiae from each)			
Mean initial weight in g.	39.0 $\pm$ 1.1	44.3 $\pm$ 0.9	33.4 $\pm$ 1.6
Mean final weight in g.	52.6 $\pm$ 1.4	49.2 $\pm$ 1.4	35.6 $\pm$ 1.8
Mean phosphatase activity (mg. P/hour/bone)	1.57 $\pm$ 0.03	1.67 $\pm$ 0.06	1.27 $\pm$ 0.05
Diff.		0.1	0.40
$\frac{P.E._{diff}}{Mean \text{ phosphatase activity} \times 100}$		0.0671	0.0781
$\frac{Mean \text{ phosphatase activity} \times 100}{Mean \text{ final weight}}$	3.0	3.4	3.57
Calcification <i>in vitro</i> at $Ca \times P = 60$	2 ( + + + + ) 3 ( + + + + )	None	2 ( + + + + ) 3 ( + + + + )

3 animals in each group were removed for observation of *in vitro* calcification, the rest of the tibiae being used for determination of phosphatase activity at  $p_H$  8.8. Group C was transferred after 21 days to the calcium rachitic diet. On each of the subsequent 3 days two animals were killed, and the tibiae used for observation of *in vitro* calcification. At the end of the third day the tibiae were similar in *in vitro* calcifying power to those of the control rats. The following day the remaining five animals of Group C were killed and the tibiae used for the determination of phosphatase activity at  $p_H$  8.8. The results of this experiment are tabulated in Table IV.

From Table IV it can be seen that the mean phosphatase values of the control group and the strontium-fed group are again close to each other. In contrast to the previous experiment the strontium group here has somewhat higher values. At any rate, this difference is without significance when examined statistically. The mean phosphatase values of the strontium-fed group which had been transferred to the calcium rachitic diet appear to be significantly lower than either one of the other two groups. However, if the smaller size of the animals in this group is taken into consideration, the values are near those of the other two groups. Certainly, there is no increase of phosphatase activity in the last group as one might expect if this enzyme were involved in the restoration of *in vitro* calcifying power. It seems evident, therefore, from these experiments that the phosphatase activity of the bone is not involved in the markedly reduced calcifying ability of the bone cells in animals suffering from rickets due to strontium.

#### SUMMARY.

1. Comparative determinations of the phosphatase activities of bones obtained from rats with strontium and those with calcium rickets were made. It was found that there was no significant difference in the phosphatase activities in similar anatomical portions of the bones from the two groups of animals.

2. The phosphatase contents of the bones of animals which were transferred from a strontium to a calcium rickets-producing diet were also determined. The mean phosphatase value of this group was somewhat less than that of the previous two groups, but when adjustments are made for the smaller mean weight of this group the mean value approaches those of the other groups.

3. Strontium ions did not affect the hydrolysing activity of phosphatase even in concentrations as high as 80 mg. of  $Sr^{++}$  in 100 ml. of hydrolysing mixture.

4. From this evidence it is concluded that there is no relationship between the marked loss of *in vitro* calcifying power and phosphatase activity in the bones of animals suffering from strontium rickets.

# CCCXIV. THE ACTION OF CHOLINE AND OTHER SUBSTANCES IN THE PREVENTION AND CURE OF FATTY LIVERS.

BY CHARLES HERBERT BEST AND HAROLD JOHN CHANNON.

*From the Department of Physiology, the University of Toronto, and the  
Department of Biochemistry, the University of Liverpool.*

*(Received September 26th, 1935.)*

THE discovery that the choline content of the diet exercises a controlling influence on the amount of fat in the liver has provided the means for many investigations into the subject of fat metabolism, and the results already obtained have illustrated a number of aspects of the problems involved. Several new factors have come to light concerning the precautions which are necessary in order to study the action of choline and we feel that at this stage it would be helpful to other workers in the field briefly to review the conditions which must be fulfilled in studying these choline effects in various types of experiment. This seems the more important because it has come to our knowledge that certain workers have encountered difficulty in detecting the results of choline administration and this we believe to be due to a lack of appreciation of all the precautions necessary in the preparation of the experimental diets. Further, some of the results from our own two laboratories seem to be in contrast and it may be helpful to show that these results, which relate to experiments carried out under somewhat different conditions, are in fact not at qualitative variance but differ only in degree.

Choline has been shown to exercise prophylactic and curative effects on the "fat" fatty liver and the "cholesterol" fatty liver produced under a variety of experimental conditions and we propose first to discuss the "cholesterol" fatty liver. Before proceeding further it is to be emphasised that throughout this paper the discussion concerns experiments which have been carried out on rats and that it is yet to be determined to what extent these results apply to other species.

Best and Ridout [1933] investigated the action of choline in preventing the increase in the amount of the liver lipoids which occurs when a diet containing cholesterol is administered to rats. By estimation of the ether-soluble hydrolysis products of the liver (fatty acids and unsaponifiable matter) they showed that choline administration prevented the accumulation which occurred in the absence of choline. Quantitative experiments suggested that the amount of choline necessary to maintain livers at their normal lipid content was of the order of 190 mg. per rat per day. These results were extended by Best *et al.* [1934] who analysed the individual liver lipoids of groups of animals receiving a cholesterol-containing diet, with and without the addition of 230 mg. of choline per animal per day. This amount of choline was found completely to prevent the glyceride infiltration, for the livers of the control animals contained 9.50 % of glyceride as against 1.51 % for those which received choline. Further, although it did not prevent the accumulation of cholesteryl esters completely, it was preventive to the extent of some 60 %. (Control 4.35 %; animals receiving choline 1.77 %; normal 0.0 %.)

Further results on this preventive action of choline on the "cholesterol" fatty liver have been obtained at Liverpool and will be published in detail in due course. They confirm however that choline has a very marked effect in preventing the accumulation of glyceride in the "cholesterol" fatty liver, as inspection of the figures recorded in Table II will show. In these particular experiments the animals received a constant amount of choline, about 75 mg., and the liver glyceride was prevented from rising by 23.8, 12.77, 3.85 and 0.21 % of the fresh liver weight. These experiments were carried out under conditions which caused varying degrees of glyceride infiltration in the livers of the control groups of animals. They show that, where the amount of liver glyceride is high in the absence of choline, administration of that substance causes a very striking decrease. When the liver glyceride is at a lower level, pronounced decreases also result, although the ease of removal of glyceride appears less than in those cases where the amounts of glyceride are high.

Turning now to the curative as opposed to the preventive action, Best and Huntsman [1935] showed that the "fat" fatty liver caused by feeding to rats a diet of mixed grain with 40 % of beef fat could be cured in 12 days by the administration to each animal of 5 mg. of choline daily, and Channon and Wilkinson [1934] reported curative experiments carried out on similar lines on the "cholesterol" fatty liver. The conclusion from these experiments was that in 10-12 days choline exerted no curative effect on the cholesteryl esters of the liver but did cause a slight decrease in the glyceride content. It is to be emphasised at this point that the "cholesterol" fatty livers produced in these experiments happened to be livers in which the glyceride content was low and of the order of 6 %. Best and Ridout [1935] then recorded the results of similar experiments, but in contrast showed that choline given in the amount of 100 mg. per rat per day caused a rapid fall in the glyceride in the period under discussion, although the finding that there was no effect on the cholesteryl esters in this period was confirmed.

The contrast in these results is apparent rather than real, for it has become clear that both ease of removal and the degree of prevention of the liver glyceride in "cholesterol" fatty livers depend in part on the initial glyceride level. In the curative experiments of Channon and Wilkinson the initial level of liver glyceride was low and in the short term experiment little effect was seen. In the results of Best and Ridout [1935] the initial level was high and a marked effect was seen. This result, which has been confirmed in the Liverpool laboratories, is further illustrated in preventive experiments by the figures recorded in Table II.

The conclusion to be drawn therefore from the results from the two laboratories is that choline will very readily prevent the accumulation and cause the removal of the glyceride present in the "cholesterol" fatty liver, but that the degree to which these effects are obtained depends to some extent on the initial glyceride concentration.

Considering now the cholesteryl ester fraction it may be stated that in neither laboratory have experiments yet been carried out in which choline has entirely prevented the accumulation of cholesteryl esters in the liver, although, as already pointed out, a prevention of up to 60 % has been observed. The conditions of these experiments in both laboratories have however been drastic in that the diets have contained 2 % of cholesterol and 20 % of fat. In curative experiments choline has little, if any, effect on the cholesteryl esters in 10-12 days when large doses of cholesterol are used. It is to be noted however that Best and Ridout [1935] reported results which show that, whilst some mechanism exists

for the removal of cholesteryl esters from the liver in the absence of dietary choline, the presence of choline in the diet caused an accelerated rate of removal which began after some 18 days. Experiments of this duration have not been carried out in Liverpool. It is clear from all the work so far carried out that both the preventive and curative actions of choline on the cholesterol fraction of the liver are much less pronounced than those on the glyceride.

The next point to be considered is the precautions which must be taken if the results of the administration of small amounts of choline are to be observed and this leads to discussion of dietary substances, other than choline, which also exercise control on liver fat. In their original work Best and Huntsman [1932] observed that betaine also possessed a lipotropic action. More recently results from both our laboratories show that a dietary constituent, the chemical nature of which has yet to be determined, is present in the protein fraction. In this paper the term "protein fraction" is used in the general sense, without defining in any way whether the lipotropic activity associated with it is due to an integral part of the protein molecule as such or associated as a contaminant.

The first work on this subject appeared when Best and Huntsman [1935] reported some experiments concerning the effect of transferring animals which had fatty livers (fat 10% and 13.5%) to a diet of pure sucrose. They found that such a transfer resulted in an average increase of liver fat by some 8%. If a diet of 80% sucrose and 20% caseinogen were used however this increase did not occur. Assuming daily consumption of 10 g. of the diet per animal this means that 2 g. of caseinogen had prevented an 8% rise in liver fat. Meanwhile Channon and Wilkinson were investigating this lipotropic effect of protein from another point of view by feeding experiments on normal animals and during the course of that work became aware of the results which had been obtained at Toronto. In reporting their results, however [Channon and Wilkinson, 1935], they inadvertently failed to make reference to this Toronto experiment. Because of the low percentage of glyceride (5-7%) which appeared in the "cholesterol" fatty livers mentioned on p. 2652, it seemed to them that some other factor besides dietary choline must be involved in controlling the glyceride infiltration and they accordingly carried out a series of experiments on the "fat" fatty liver in which the fat content of the diet was maintained at a constant level, 40%, while the protein (caseinogen) content of the diet (0-50%) was varied at the expense of the carbohydrate (glucose). Their conclusions from these experiments were that the amount of fat appearing in the liver was determined by the amount of protein in the diet, irrespective of any action of choline.

This paper was followed by one from Best, Huntsman, McHenry and Ridout [1935] in which it was stated that, when the fat content of the diet was 20% (Channon and Wilkinson used 40% fat) and the protein content as high as 15-20%, rapid accumulation of glyceride appeared in the liver. Further, even when the fat content was as low as 3%, glyceride still appeared in the liver, provided that the amount of lipotropic substances in the diet was very small. The results recorded in that paper were concerned with feeding experiments in which a relatively fixed percentage of protein was employed (15-21%): the finding that such a protein percentage yet permits fatty livers on diets containing as little as 3% of fat must not be interpreted as indicating the absence of a lipotropic effect from the protein fraction and therefore as being opposed to those of Channon and Wilkinson [1935]. Experiments have since been carried out in Toronto by methods which were the same as were used by the Liverpool workers, save that the diets were essentially choline-free and were administered to much larger groups of animals. The more complete results which these

experiments have given confirm the findings of Best and Huntsman [1935] and are in complete harmony with those of Channon and Wilkinson that in the conditions of these experiments the protein fraction of the diet exerts a lipotropic effect. These latter authors have further confirmed their previous findings and have also extended them to a study of the "cholesterol" fatty liver problem with the same results. The further data from the two laboratories, showing the lipotropic action of dietary protein, will be published in detail in due course.

The next point for consideration is the means whereby the protein fraction of the diet exercises this lipotropic effect. Various suggestions have been made as to the mechanism of this action [Best and Huntsman, 1935; Channon and Wilkinson, 1935; Best, Huntsman and Ridout, 1935] and in order to dispel any possible confusion as to our views it is to be stated that in neither laboratory has evidence yet been obtained as to whether the protein is exercising its effect through an amino-acid or some other integral part of the protein molecule, or whether there is some contaminating lipotropic substance. It can now definitely be stated however that contaminating choline can account for only an insignificant part of the caseinogen effect. Should some aspect of protein metabolism be involved in the lipotropic effect, the experiments at Liverpool, in which the action of pure amino-acids, and at Toronto where the lipotropic effects of the fractions of protein hydrolysates, are being investigated, should provide further information.

It is not possible on the basis of the figures available adequately to compare the lipotropic effects of the protein fractions used in our two laboratories. Such figures as are available have been obtained in experiments of different types. In the original experiments of Best and Huntsman [1935] 2 g. of protein caused a decrease of 8% in the liver fat, and Best, Huntsman and Ridout [1935] expressed the view that 2 g. of their caseinogen had the equivalent effect of 1 mg. of choline. In preventive experiments in Liverpool 2.5 g. of protein have generally lowered the liver fat by 20%. Accurate comparisons cannot be made however until the lipotropic effect of the proteins is assessed in terms of choline and this is at present under investigation. Meanwhile we have the general impression that the protein fractions used in Liverpool may possess lipotropic actions greater than those used in Toronto.

For the benefit of other workers it may be useful to discuss the question of the percentage of liver fat which may result from diets of varying fat and protein contents and the conditions necessary for obtaining high liver fat levels. Here difficulties arise because of complicating factors concerned with the composition of the diets, the chief of which is the provision of vitamin B<sub>1</sub>. Dried yeast and certain yeast preparations which are commonly used as sources of vitamin B<sub>1</sub> may contain considerable amounts of choline. In Toronto this difficulty has been overcome by the use of crystalline vitamin B<sub>1</sub>, which has been made available through the generosity of Messrs Merck. In Liverpool, because it has not been found possible to obtain samples of crystalline vitamin B<sub>1</sub>, it has been the practice to use 5% marmite in the diet in order to supply this vitamin. Biological assays on this material, carried out both at Toronto and repeatedly in Liverpool, show that marmite contains about 3 mg. of choline per g., so that on a daily intake of 10 g. a rat receives 1.5 mg. of choline from this source. It is possible also that there may be present in marmite some other substance which exerts a lipotropic action, but such evidence as is available at the present time does not appear to support that possibility.

Since Best and Huntsman [1935] amply demonstrated the preventive effect of 5 mg. of choline in "fat" fatty liver production, it is clear that the daily intake

of the 1.5–2 mg. present in 0.5 g. marmite must render any comparison between the liver fat levels obtained in the two laboratories very uncertain. In experiments in which the diets contained the same amount of fat but considerably more protein, Best, Huntsman and Ridout [1935] obtained considerably higher liver fat levels than those obtained in Liverpool and it was on this finding that they based the statement that comparison of the results from the two laboratories did not appear to show that a lipotropic effect of protein *per se* was apparent. These authors did not intend to convey the impression that they believed that the protein fraction was not exerting a lipotropic effect: in fact, they had observed this effect repeatedly. Further, it may be stated here that it is very difficult to compare the results from the two laboratories when findings which may be affected by such factors as the type of protein fraction, the exact nature of the carbohydrate *etc.* are under discussion. In diets used in the two laboratories, where the only apparent substantial difference is the presence of vitamin B<sub>1</sub> or marmite, the general tendency must clearly be for higher levels of liver fat to appear in the Toronto results than in the Liverpool ones, although the general effects will not be obscured by the marmite, unless the particular diets are such as to cause a relatively low degree of fat infiltration. The Toronto workers [1935] quoted an average fat content of the livers of 50 animals receiving a diet of 40 % fat and 21 % protein for 3 weeks of 17 % and contrasted this with the 12 % found originally by Channon and Wilkinson in animals receiving the same amount of fat and one-quarter the amount of protein. The figures recorded by Channon and Wilkinson happened in that particular experiment to be at an unusually low level, possible reasons for which are discussed later. The mean value for all the 87 animals which have received this 5 % protein diet with 40 % of fat since those original results is however 24.6 %. Bearing in mind that in every case the diet has contained some 2 mg. of choline present in the marmite, it is yet clear from these subsequent results that the lipotropic effect of the protein fraction is demonstrated, even by comparison with the 17 % figure recorded by the Toronto workers for a diet containing 21 % protein. Thus on these figures it is possible that the protein *per se* is exerting an effect, but it is obvious from what we have already stated that the lipotropic action of the protein fraction may prove to be due in part or completely to a contaminating non-choline lipotropic factor. Such comparison also seems to indicate that lipotropic substances other than choline or protein are not present in the marmite to any significant extent.

It is probably the presence of marmite in the diet which explains the lack of consistency compared with other results in some of the experiments reported by Channon and Wilkinson, a point to which the Toronto workers have drawn attention.

The next point to be discussed is the effect of weight losses by the animals on their content of liver fat. Channon and Wilkinson [1935] neglected the result of one of their experiments in which every animal lost weight. Best, Huntsman and Ridout [1935] however recorded a large series of figures showing that there was no correlation between weight losses in animals on a given diet and their liver fat content. Although similar results had been obtained in Liverpool, showing that on a diet which caused slight gains in weight in some animals and slight losses in others the weight change was not related to the liver fat, Channon and Wilkinson thought it unwise to base deductions on the results of the one group of animals in which weight losses had been experienced by every animal. In all the other groups the average weight change had been from  $-0.6\%$  to  $+31.6\%$ , whereas in this particular group the average weight change was  $-12.6\%$ .

As pointed out in a preceding paragraph, the mean value for the liver fat of 87 animals receiving the 5% protein diet has been 24.6%, as against that of 12% originally reported, and a brief discussion is necessary on this very considerable increase. The limited groups of 6 animals which were previously used must necessarily be a factor, but cannot account for more than a small part of the difference. The Toronto workers in their earlier work pointed out that at times they failed to obtain fatty livers in groups of animals on diets which produced fatty livers in other groups of animals and no explanation of this finding is yet forthcoming. Further, they have emphasised that it is necessary in every experiment to use control groups, because even animals from the same stock do not consistently give the same figure for liver fat content when put on the same diet at different times. In Liverpool this latter observation has been confirmed many times. There appear therefore to be other factors yet to be determined which cause this variation in liver fat level. One of these clearly may be temperature, and in this connection it may be stated that when the experiments of Channon and Wilkinson were carried out the animal house was not thermostatically controlled. Further, the extreme susceptibility of the liver fat to change is illustrated by an experiment of Best and his colleagues, who observed that frequent handling and subcutaneous injection of saline had an interfering effect. The reasons for these varying results from groups of animals on the same diet clearly need further investigation.

The preceding discussion will, it is hoped, clarify the conditions necessary for the study of the effects of choline in the fatty liver problem and we think that lack of appreciation of some of these conditions has been responsible for difficulties which may have been encountered by other workers.

Obviously the ideal diet would contain no substance having any lipotropic effect. This means that in the first place the diet must be choline-free, as can be demonstrated by hydrolysis of the constituents and biological assay of the acetylated products on the isolated rabbit intestine. Secondly some of the food constituents of the diet may contain betaine or substances of the betaine class, or other unidentified lipotropic factors. No method of estimating these is available. Lastly, even in the absence of any of these substances, dietary protein itself may exercise a lipotropic effect. As already pointed out, one of the main difficulties is the provision of vitamin B<sub>1</sub>, without which the diets on the whole are poorly consumed. Crystalline vitamin B<sub>1</sub> is obviously the most satisfactory material but, if it is not available, care must be taken to choose a material containing as little choline as possible. Unless the diet is extremely low in lipotropic substances (*i.e.* equivalent to less than 1 mg. of choline per day), the effects of choline administration will not be observed in experiments in which the dietary conditions are less drastic. The main difference which exists between the Toronto and Liverpool results under discussion is connected with this factor and may be summarised by saying that on diets of similar composition, differing only in the provision of vitamin B<sub>1</sub> in crystalline form or as marmite, livers reach a higher level of fat content in Toronto than in Liverpool. It may be stated that with diets of constant protein content, but of variable fat content, the degree of fat infiltration in the liver increases with the fat content, and further that with diets of constant fat content the liver fat increases with decreasing protein content. The most intense degree of fat infiltration will be produced when the diet is high in fat and when the protein fraction is kept at as low a level as is desirable, with the diet free also from other lipotropic substances.

Lastly, because of the difficulty which some other workers appear to be experiencing in demonstrating the effect of choline, we consider it of value to

Table I. *Preventive action of choline on the "fat" fatty liver.*

Exp. No.	Duration of exp. (days)	Control		Control + choline			Fall in glyceride caused by choline administration %
		No. of animals in group	Liver fat %	No. of animals in group	Liver fat %	Choline/ rat/ day (mg.)	
B 1	21	9	20.8	10	5.65	79.0	14.1

Wd	21	10	2.92	10	2.71	74.0	0.21

refer to results which have been secured independently in Liverpool. These results have been obtained, not with the specific purpose of demonstrating the already well established effect of choline, but merely as a routine in order to assay the lipotropic effect of other substances in terms of choline. In Table I therefore is recorded a series of preventive experiments on the "fat" fatty liver. The figures in Table I show the striking effect of choline in preventing the accumulation of fat in the liver. No figures are available concerning the minimum amount of choline which will result in a preventive, if not a completely preventive, action. On diets containing 40% of fat the above figures show however a decrease of 21.5% caused by 20 mg. of choline and one of 17.3% caused by 8.7 mg. of choline, although in neither case has the liver fat reached the normal level of 4%, results which amply confirm the Toronto finding as to the effective action of small amounts of choline.

In another series of Liverpool experiments the preventive action of choline on the "cholesterol" fatty liver has been studied and Table II records some of the results concerning the effect on the glyceride fraction. Here again no attempt has been made to reach the minimum figure showing a preventive action.

#### SUMMARY.

1. Present knowledge regarding the action of choline and other substances in the prevention and cure of fatty livers induced by dietary means is discussed and the results obtained from the laboratories at Liverpool and Toronto are shown to be not at qualitative variance but to differ only in degree, governed by the somewhat different conditions under which experiments have been carried out.

2. The protein fraction of the diet exercises a controlling influence on the amount of the liver lipoids. Possible means whereby this lipotropic action of the protein fraction exerts its effect are discussed.

3. The precautions necessary for planning diets adequate for observing the effects of choline are considered in detail.

4. Figures which have been obtained independently in Liverpool on the preventive action of choline on the "fat" and "cholesterol" fatty livers are recorded. They confirm the findings obtained at Toronto.

The expenses of the work carried out at Liverpool have been borne from an expenses grant from the Medical Research Council, for which grateful acknowledgment is made.

# CCCXV. THE INFLUENCE OF THE CASEINOGEN CONTENT OF DIETS ON THE NATURE OF THE "CHOLESTEROL" FATTY LIVER.

By ALAN WILMOT BEESTON, HAROLD JOHN CHANNON  
AND HARRY WILKINSON.

*From the Department of Biochemistry, the University of Liverpool.*

*(Received October 31st, 1935.)*

IN continuation of investigation of factors influencing the nature of the "cholesterol" fatty liver, Channon and Wilkinson [1935] carried out experiments in which the percentage of protein (caseinogen) in the diet was varied at the expense of the carbohydrate (glucose). The results of those experiments, which were carried out with relatively small groups of animals in investigations concerned with the production of the "fat" fatty liver, indicated that the amount of glyceride in the "fat" fatty liver was governed by the amount of caseinogen in the diet. A further experiment of similar nature on the "cholesterol" fatty liver was reported. The livers of animals receiving 5% caseinogen in the diet contained 19.88% (wet liver weight) more glyceride than did those of other animals receiving 30% of the protein. Criticisms of some of the individual experiments recorded in that paper have been made by Best, Huntsman and Ridout [1935]; since these have been discussed in a joint paper from the two laboratories, they need not be referred to further [Best and Channon, 1935].

The present paper is concerned with an extension of this experiment on the "cholesterol" fatty liver, in order to confirm the lipotropic action of the protein fractions of diets containing cholesterol on the glyceride content of the liver and to study whether any effect was also exercised on the lipoid constituents other than the glyceride; to attempt thereby experimentally to produce "cholesterol" fatty livers of varying glyceride content; to study the preventive action of choline on such livers in the hope of throwing light on the question of whether choline affects the cholesterol fraction directly or only indirectly by virtue of its action on the glyceride; and further to seek evidence which might differentiate the lipotropic action of dietary protein fractions from that of choline.

## EXPERIMENTAL.

The first experiment was carried out by analysing the pooled livers of groups of animals by the methods previously used after 3 weeks' feeding on diets containing varying percentages of caseinogen. The materials which were in constant proportions in the diets of all the groups of animals were: beef dripping 20, cholesterol 2, salt mixture 5, marmite 5, with one drop of cod-liver oil per animal every 3 days. The four diets differed however in that the protein content (caseinogen, 5, 10, 15 and 30 parts) was varied at the expense of the carbohydrate (glucose, 63, 58, 53 and 38 parts). The caseinogen had been previously extracted industrially and was further extracted several times with hot alcohol-ether mixture before use.

Each group of animals consisted of 5 bucks and 5 does, chosen so that one animal of each sex of as nearly as possible the same weight was present in each group. The average initial weights of the animals in the groups receiving 5, 10, 15 and 30 % caseinogen in the diet were 155, 158, 155 and 151 g. respectively. Two animals in group 1 and one animal in group 2 died during the experiment. At the end of the experiment there were 8, 9, 10 and 10 animals in the four groups respectively. The corresponding average changes in body weight at the end of the experiment, calculated as percentage of the initial value, were 0.0, +11.1, +18.0 and +17.0 %.

The animals were allowed food *ad libitum* and at the end of the experiment were killed 24 hours after the last feeding. In order to obtain the livers in as comparable a state as possible from the point of view of their blood content, a guillotine was used for the killing and the liver dissected from each animal after as much blood as possible had been drained from the body. It was hoped that this precaution might help to avoid some of the variations which have been previously encountered in the percentages of liver fat in individual animals and this method of killing has now been adopted as routine.

The results of this experiment are recorded in Table I. Before discussing the results it is necessary to emphasise that, save for the protein and carbohydrate fractions, the diets were of constant percentage composition for all four groups. By biological assay the choline content of this constant fraction of the diet was found to be such that each animal received less than 2 mg. of choline per day, the marmite contributing practically the whole of this amount. The only difference in the intake of choline from this fraction of the diet by the different groups depended on the differences in food intake, which were small. Consequently in considering any possible effect of choline in relation to that of the protein fraction, the choline content of the latter only has to be taken into account. This was determined several times in this Department and was found to be 0.8-1.2 mg./100 g. In order to obtain confirmation of this figure a sample was submitted to Prof. Best, who very kindly carried out independent determinations at Toronto and reported a figure of less than 5.0 mg./100 g. Any possible choline content of the glucose can be neglected because, if choline were present in that material, it would diminish any effect shown by decreasing the protein content of the diet. Figures for the average daily intake of choline by the different groups are recorded in Table I.

Table I. *Percentage of lipoids present in the livers of rats receiving diets containing 20% fat and 2% cholesterol with varying percentages of caseinogen (g./100 g. fresh liver).*

Group no. ...	1	2	3	4
Caseinogen content of diet, %	5	10	15	30
Liver as % of final body weight	6.09	5.35	5.18	4.45
Choline intake (mg./rat/day)	1.65	1.80	1.79	1.55
Lecithin, %	1.71	2.31	2.83	3.14
Cholesterol, %	0.29	0.32	0.35	0.37
Cholesteryl oleate, %	5.89	7.26	8.30	9.72
Glyceride, %	32.75	21.42	14.06	4.23
Total, %	40.64	31.31	25.54	17.46

The figures in Table I show the striking effect of varying the caseinogen content of the diet at the expense of the carbohydrate in increasing the percentage of the total lipoids present. Inspection of the figures for the individual constituents shows that with the increase of the protein fraction of the diet

from 5 to 30 % there are consistent progressive increases in the percentages of lecithin (1.71 to 3.14 %), cholesterol (0.29 to 0.37 %), and cholesteryl ester (5.89 to 9.72 %), in a manner which might suggest a direct effect of the protein fraction in controlling these constituents in the conditions of these experiments. Further, the percentage of the glyceride increases profoundly in the reverse direction, for group 1 (5 % protein) contains 32.75 % as compared with group 4 (30 % protein) which contains 4.23 % with a regular gradation in the intermediate groups. All these findings are confirmed by groups 5*a*–8*a* in Exp. 2 to be described later.

The results appear to be dissociated from any effect of choline. In the first place the amount of caseinogen ingested by groups 1 and 2 differed by approximately 0.5 g. per animal daily and this has caused a decrease of 11.33 % in the glyceride content calculated on the fresh liver weight. On a choline content of 5 mg./100 g. this ingestion of 0.5 g. of caseinogen corresponds to an extra choline intake of 25  $\gamma$  over the control group, an amount far too small on all present evidence to have so striking an effect. It is remotely possible that the glucose contains a substance which has a marked effect in causing deposition of glyceride in the liver and, if this were so, the results would be explained on that basis, but this possibility seems so remote that it is not profitable to discuss it further at the present time. On these results therefore the ingestion by each animal of an extra 0.5 g. of caseinogen daily has caused a decrease in the liver glyceride of 11.33 % between groups 1 and 2, and 7.36 % between groups 2 and 3, whilst an additional 1.5 g. daily has caused a decrease of 9.83 % between groups 3 and 4. These results therefore fully confirm the finding of Channon and Wilkinson [1935] that the amount of the protein fraction of the diet controls the percentage of glyceride in the "cholesterol" fatty liver, and they show that a similar but more limited control is exercised in the reverse sense on the percentages of lecithin and of cholesterol and its esters.

The only available figure showing the effect of dietary protein fractions in decreasing the glyceride content of the liver is that observed in the experiment of Best and Huntsman [1935], who recorded the first observation of this lipotropic effect on the liver glyceride. These authors found that transfer of animals already having fatty livers to a diet of pure sucrose caused an increase in the liver fat of some 8 %. After a similar transfer to a diet consisting of 80 % sucrose and 20 % caseinogen however this increase did not occur. In their experiment therefore a daily intake of 2 g. of caseinogen prevented an 8 % rise in the liver glyceride, although it did not cause the high initial value to fall. The very different conditions of these experiments however prevent any significant comparison of our results with those of the Toronto workers being made at the present time.

It has been pointed out that on the percentage figures in Table II the increase of the percentage of the protein fraction in the diet appears to cause significant and steady increases in the lecithin, cholesterol and cholesteryl ester fractions. These percentage figures, although instructive from one point of view, do not yield accurate information as to the extent to which the liver is acting as a reservoir, because of the great increase in the size of the livers which occurs when they become loaded with cholesteryl esters and glyceride. Thus in group 1 the liver constituted 6.69 % of the final body weight, whereas in group 4 it was but 4.45 % with intermediate figures between these values.

For this purpose it is therefore necessary to compare the actual weights as opposed to the percentages of the individual constituents in the liver. Since the average initial weight of the animals in the groups was approximately constant, the amounts of each lipid constituent in the livers of each group may be

Table II. *Weight of lipoids in the liver of the 100 g. rat, calculated on the final and initial body weights (g.).*

		Percentage of protein in diet			
		5	10	15	30
Lecithin	Calculated on				
	Final body wt.	0.115	0.124	0.146	0.140
	Initial "	0.115	0.137	0.173	0.163
Cholesterol	Final "	0.020	0.017	0.018	0.016
	Initial "	0.020	0.019	0.022	0.019
Cholesteryl oleate	Final "	0.396	0.390	0.430	0.433
	Initial "	0.396	0.432	0.508	0.505
Glyceride	Final "	2.178	1.149	0.728	0.189
	Initial "	2.178	1.273	0.859	0.220
Totals	Final "	2.709	1.680	1.322	0.778
	Initial "	2.709	1.861	1.562	0.907

compared at the end of the experiment, if changes in body weight during the experiment be disregarded. This entails reference to the average animal. An alternative method is to refer all the results to the 100 g. rat and this is preferable for comparison with other results. In order to determine whether the average change in body weight, which occurred during the experiment and which varied from 0 to +18% in the different groups, plays any part in the interpretation of the results, we have calculated the amounts of the different lipoids in the liver of the 100 g. rat when referred both to the final and initial body weights respectively. This latter figure will of course correspond to that of the average animal at the end of the experiment as mentioned above, in which any body weight change occurring during the experiment is neglected. The figures so obtained will not represent quite accurately the amounts of the constituents which would have occurred in the livers if rats weighing 100 g. had been used, because liver size does not bear an entirely linear relationship to body weight. This factor however is sufficiently unimportant to be disregarded, and in any case the results from the different groups may be compared with each other.

A number of points emerge from Table II. In the first place, it is clear that whichever method of reference be adopted, the actual weight of lecithin present in the liver increases as the percentage of the dietary protein fraction is increased, at least up to 15%. This result is confirmed by the results of Exp. 2 (groups 5a-8a, Table V), where the increase continues to the 30% protein group also (group 8a). Thus the absolute weight of lecithin is increased as are the percentages recorded in Table I.

On the other hand whilst the free cholesterol is increased in all cases above normal, such slight differences as occur between the different groups are inconsistent and it is clear that the graded percentage increases recorded in Table I are merely the result of a dilution effect, the percentage falling as the liver increases in size, with decrease in the dietary protein percentage. This result also is borne out by those of Exp. 2 (Table V).

With regard to the cholesteryl ester fraction the figures are not conclusive. Whilst the lower values occur in the groups receiving less caseinogen in the diet, and the higher values with increase of dietary protein, there is no progressive change. The results in Exp. 2 (Table V) also bear this out. In two other experiments in which diets containing 5% and 30% caseinogen were used, the absolute amounts of cholesteryl ester per 100 g. rat were 0.245 and 0.246 g. for 5% protein and 0.281 and 0.308 g. for 30% protein. Yet a further experiment gave for 10% and 50% of caseinogen in the diet for 14 days 0.164 and 0.211 g.

respectively. Thus whilst there is a general tendency for the absolute amount of cholesteryl ester in the liver to be increased by increase of the amount of dietary protein consumed, no significance can at present be assigned to this finding. Thus, as in the case of the free cholesterol, the effect of lowered dietary protein in decreasing the percentage (Table I) may be a dilution effect only.

Lastly, Table II shows that virtually the whole of the difference between the amounts of total lipoids in the livers of the four groups depends on differences in the glyceride contents. The glyceride of group 1, 2.178 g., is some 60 times that of a normal liver; with increasing protein this decreases until with 30 % of caseinogen in the diet it is only 5 times that of the normal. We have no figures for the total reserve fat of animals on these particular diets, or any proof of the source of the liver glyceride. If it be assumed however that the liver glyceride has been derived from the fat depots and that the total depot fat of a 100 g. rat is 12 g., it is seen that the 5 % protein diet has caused the appearance in the liver of about one-sixth of the total reserve fat.

As regards the quantitative aspect of the caseinogen effect, Table II shows that when referred to group 1 the ingestion of an extra 0.5, 1.0 and 2.5 g. of caseinogen in groups 2, 3 and 4 has prevented the appearance in the liver of 1.029, 1.450 and 1.989 g. of glyceride respectively. The preventive effect of increasing the dietary protein fraction is thus the more strikingly shown at the lower levels.

One further point worthy of notice is that, whether the results for the different constituents be compared on the basis of the initial or final body weights, the general trend of each series of figures remains the same, even though the figures individually are somewhat changed.

Further work is now in progress in order to equate the lipotropic action of the protein fraction of the diet with that of choline; whether this action is due to an integral part of the caseinogen molecule or to a contaminant is at present unknown [Best and Channon, 1935].

These results show therefore that the intake of dietary protein fractions governs the amount of glyceride in the "cholesterol" fatty liver. This glyceride control, first demonstrated by Best and Huntsman [1935] in a transfer experiment on animals already having "fat" fatty livers, has thus now been extended to normal animals receiving diets which cause both "fat" and "cholesterol" fatty livers [Channon and Wilkinson, 1935]. The results show further that dietary protein also controls the absolute amount of liver lecithin and possibly that of cholesteryl esters, while they provide the means whereby "cholesterol" fatty livers of different types may be readily produced.

We have therefore used this finding for further study of the action of choline in preventing the "cholesterol" fatty liver. The one recorded experiment in which the preventive action of choline on the individual liver lipoids was studied was that of Best, Channon and Ridout [1934]. These authors found that 230 mg. of choline per rat per day entirely prevented the deposition of glyceride in the livers of animals receiving a diet containing 20 % of fat and 2 % of cholesterol. From the fact that this choline administration prevented not more than 60 % of the cholesteryl ester deposition, it was concluded that the primary effect of choline was on the glyceride fraction.

The method of experiment has been essentially the same as was used in Exp. 1, save that in addition to groups of animals receiving 5, 10, 15 and 30 % of caseinogen, further groups have received similar diets with the addition of choline chloride (1 %). On the food intakes, which were measured daily, the amount of choline ingested per rat per day varied from 80 to 74 mg. in groups

5*b*–8*b* respectively, whilst the corresponding control groups (5*a*–8*a*) received approximately 2 mg. daily in the basal diet.

The percentage composition of the liver lipoids of the two series of groups of animals are set out in Table III. If the effect of the dietary protein fraction be first considered (control groups 5*a*–8*a*) it is seen that the various liver lipoid

percentages bear out the findings of Exp. 1 in every respect and they need therefore no further discussion. The only further point worthy of notice in this connection is that whereas in Exp. 1 the total lipid percentages in the groups 1–4 (5–30% caseinogen) varied from 40.64 to 17.46%, in the present experiment they range from 32.12 to 14.80%. Two other experiments carried out under identical conditions with 5 and 30% of caseinogen gave 31.92–16.44% and 38.54–16.41% respectively. The difference in the results from series of groups of animals which have received the same diet for the same period but at different times has no explanation at present. Some possible reasons for this phenomenon, which frequently occurs, have been discussed by Best and Channon [1935].

Further discussion of the figures in Table III will be confined therefore to mention of the preventive effect of choline on the different lipid percentages, because the action of this substance on liver "fat" has been usually discussed on this basis. The addition of choline has significantly increased the percentage of lecithin in all the groups where the glyceride percentage was high (*cf.* 5*b*–7*b* with 5*a*–7*a*). It has had little effect on the percentages of free cholesterol, but has caused a marked and regular decrease in those of the cholesteryl ester fractions of all the groups. Its chief effect however is on the glyceride fractions where the striking preventive action of the 80–74 mg. given per rat per day is shown in all the groups. Thus in group 5*b* the glyceride is at the normal level, whereas the control group, 5*a*, contains 24.78% glyceride. Similarly group 6*b* contains 3.4% as compared with the 16.17% of its control, 6*a*. The percentage of glyceride in groups 6*b*–8*b* varies from 3.40 to 2.7%, figures which are about 2% above normal. It appears therefore that the deposition of cholesteryl esters causes the accumulation of some 2% glyceride in spite of the presence of a considerable amount (1%) of choline in the diet.

The figures in Table IV, in which the absolute weights of the liver constituents are calculated on the basis of the 100 g. rat on the final body weight, do not differ significantly from those calculated on the average animal (initial

Table IV. *Weight (g.) of individual lipoids present in the liver of the 100 g. rat (calc.).*

Group no. ...	5a	5b	6a	6b	7a	7b	8a	8b

body weight) and the latter are therefore not recorded. The findings of the effect of increasing the dietary protein fraction discussed under Exp. 1 appear confirmed, and the effect of choline may now be considered in relation to the latter.

It is of interest to discuss whether any conclusion may be drawn from the figures in Table IV, as to whether lecithin is functionally active in controlling the

Table V. *Degree of prevention of glyceride and cholesteryl ester deposition (g. liver of 100 g. rat).*

degree of fat infiltration and whether choline exercises its effect through this substance. The first point for observation is that the addition of choline has not caused any increase in the amount of lecithin in any of the four groups, even though in groups 5b and 6b it has caused a profound decrease in the total lipid constituents. This might be used as an argument that the choline effect is not exercised through lecithin, an argument which consideration of the lecithin figures in the control groups of animals might appear to confirm. In these the amount of lecithin actually increases with increasing caseinogen intake, although the total lipoids of the liver are also rapidly falling (*cf.* 5a and 6a). Both these lines of argument are however open to possible objections; thus although choline has caused no increase in the amount of liver lecithin, it might yet be exercising its effect by enabling lecithin synthesis to occur, the newly synthesised lecithin being used for the transport of fatty acids to the tissues and being metabolised in the process, whilst the fact that there is an increase in lecithin with increasing dietary protein might be connected with an entirely different phenomenon, possibly the phosphorus content of the caseinogen. However on their face value these results suggest that the lipotropic effect of the dietary protein fraction is to be differentiated from that of choline, in the sense that whilst it prevents fatty livers and causes an increase in the amount of lecithin, choline prevents fatty livers but does not cause such an increase. We feel it wise to regard these results as being no more than suggestive.

The degree of prevention caused by the provision of choline can be more readily studied from the figures in Table V.

These figures show in relation to those in Table IV that in the four experiments choline has prevented the appearance of 97, 83, 65 and 11% of the glyceride which appeared in its absence, and that of 54, 48, 41 and 20% respectively of the cholesteryl ester. It is not possible from such figures definitely to decide whether choline is exercising a direct preventive effect on the cholesteryl

ester fraction. If its effect on the latter were dependent on a primary action in preventing glyceride infiltration, then it would have been anticipated that the figures in the two columns would have run parallel. Such however is not the case. This might suggest therefore that the action of choline in preventing cholesteryl ester deposition was independent of glyceride. In this connection it is to be observed that in groups 7*a* and 8*a* the amount of glyceride which appeared in the liver in the absence of added choline was relatively quite small compared with those of 5*a* and 6*a*. Since the amounts of choline were approximately constant for all the groups, it would have been expected, were there a direct action on the cholesteryl ester fraction, that there would have been a considerably increased degree of cholesteryl ester prevention in groups 7*a* and 8*a*, for in these two groups the choline was almost entirely free to act in this direction. The figures however do not bear this out. We feel therefore that no conclusion can be drawn as to whether there is a direct effect of choline on the cholesteryl ester fraction. It will be remembered that Best and Ridout [1935] observed that there was a process for the removal of cholesteryl esters from the liver in the absence of dietary choline, but that the rate of removal was increased after some 18 days by choline administration.

Another point which needs mention is that in these experiments the lipotropic effect of protein is confined to the glyceride fraction only, whereas that of choline affects the cholesteryl ester fraction also. This might appear at first sight to differentiate the protein fraction effect from that of choline in the way that the lecithin figures have indicated. Prof. Best has kindly pointed out to us however that, if 1 g. of protein had a lipotropic action equivalent to 3 mg. of choline, as suggested by Best, Huntsman and Ridout [1935], then this lack of effect of the dietary protein fraction on cholesteryl esters would not indicate a qualitative difference in the lipotropic action, because, say, 9 mg. of choline would have presumably little effect, if any, on the cholesteryl ester fraction.

It must be clearly realised that the amounts of choline used do not represent the minimum necessary to give a preventive effect. The object of the experiments was to choose a daily choline intake which would lie between the 230 mg. found to be completely preventive as regards the glyceride fraction by Best, Channon and Ridout [1934], and that which would have a very definite, although not completely preventive effect.

#### SUMMARY.

The effect of quantitative variations in the protein fraction of the diet on the amount and composition of the lipoids of the livers of rats receiving a diet of low choline content and containing 20 % of fat and 2 % of cholesterol has been studied in two series of experiments. Profound changes are caused in the amounts of the different lipoids in the resulting "cholesterol" fatty livers by such variation. The results are discussed on both a percentage basis and on that of the absolute weights. In confirmation of the results of Channon and Wilkinson, they show that in the "cholesterol" fatty liver the dietary protein fraction exercises a profound lipotropic effect. By the use of graded protein percentages in the diet it is thus possible to produce "cholesterol" fatty livers of widely varying composition and these findings have been used in further experiments for studying the preventive effects of choline. These experiments have shown that the addition of approximately 80 mg. of choline per rat per day very largely prevents the deposition of glyceride, but only partially prevents that of cholesteryl esters. No deductions could be made from the experiments as to whether choline is exerting its effect through lecithin synthesis, or whether

choline has a direct action in preventing cholesteryl ester deposition. The lipotropic effect of the protein fraction differs superficially at least from that of choline, in that the absolute amount of liver phosphatide is increased.

We wish to express our thanks to the Medical Research Council for a grant from which the expenses of this research have been defrayed.

Our thanks are also due to Dr J. V. Loach for biological assay of the choline content of the various dietary constituents.

# CCCXVI. POLYSACCHARIDES SYNTHESISED BY MICRO-ORGANISMS.

## II. THE MOLECULAR STRUCTURE OF VARIANOSE PRODUCED FROM GLUCOSE BY *PENICILLIUM* *VARIANS* G. SMITH.

By WALTER NORMAN HAWORTH, HAROLD RALSTRICK  
AND MAURICE STACEY.<sup>1</sup>

*From the Department of Chemistry, University of Birmingham, and the  
Division of Biochemistry, London School of Hygiene and Tropical  
Medicine, University of London.*

(Received September 27th, 1935.)

A POLYSACCHARIDE unique in its constitution has been prepared by the action of *Penicillium varians* [Smith, 1933] on glucose in Czapek-Dox medium. The mould belongs to the group Biverticillata-symmetrica and the polysaccharide, which has the empirical formula  $(C_6H_{10}O_5)_n$ , is a white amorphous powder neutral in aqueous solution and having  $[\alpha]_D +15^\circ$ . It reduces Fehling's solution slightly and gives no colour with iodine; it is almost unaffected by digestion at  $100^\circ$  with  $N/100$  HCl but is hydrolysed readily with  $N/10$  HCl at  $100^\circ$  and the scission products contain *d*-galactose to the extent of approximately 70%. The remaining portion consists of glucose (14%) and also an unidentified hexose (14%) which appears to be either *d*-idose or *l*-altrose. It is thus significant that although the only available source of carbon in the original nutrient solution was glucose this has been converted, by the subsequent metabolism involved in the synthesis of the polysaccharide, very largely into galactose and into either *d*-idose or *l*-altrose.

Inasmuch as the polysaccharide was prepared by the agency of *P. varians* it has been given the name *varianose*. Varianose is readily acetylated by the usual methods and the completely acetylated polysaccharide showed  $[\alpha]_D^{20} +30^\circ$  in chloroform and  $+38.2^\circ$  in acetone; the acetate yielded unchanged varianose on deacetylation. Completely methylated varianose was prepared by the action of methyl sulphate and potassium hydroxide on varianose acetate or on the unsubstituted polysaccharide; it was a cream-white powder, soluble in water, chloroform or benzene and showed in these solvents respectively,  $[\alpha]_D +15^\circ$ ,  $+20^\circ$ ,  $+23^\circ$ . The determination of the structure and chain length of methylated varianose was carried out by the method of Haworth and Machemer [1932]. Methylated varianose was hydrolysed with methyl alcoholic hydrogen chloride; the resulting hexosides were separated first by the use of solvents and finally by careful fractional distillation, yielding 14% of 2:3:4:6-tetramethyl-methyl-glucopyranoside which corresponds to a chain of 8 hexose members of a molecular weight of about 1300 for varianose (see formula 1). The remaining hydrolytic products consisted mainly of trimethyl-methylgalactoside which yielded on hydrolysis a liquid 2:3:6-trimethylgalactose, characterised by its oxidation with bromine water to the crystalline 2:3:6-trimethylgalactofuranolactone of Haworth *et al.* [1932]. This yielded on treatment with ammonia a

<sup>1</sup> Beit Memorial Research Fellow.

crystalline amide which served further to identify the free sugar. The positions of the three methyl groups were determined by oxidation of the crystalline lactone with nitric acid. The product contained no trace of a mucic acid derivative. From this it is inferred that position 6 in the sugar chain was protected by a methyl group inasmuch as it has been our experience that when the terminal primary alcohol group is unprotected a mucic acid derivative is readily obtained. The crystalline product isolated from this oxidation consisted of *d*-dimethoxysuccinamide and its isolation indicates that positions 2 and 3 in the trimethyl-lactone are occupied by methyl residues. Inasmuch as the trimethyl-lactone behaved in respect of its rate of hydrolysis exactly as a  $\gamma$ -lactone we also infer that position 4 was not occupied by a methyl group. Moreover, the trimethyl-sugar showed in its chemical behaviour the capacity to pass either into a furanose or pyranose form on glycoside formation. The properties therefore of the isolated trimethylgalactose are in full agreement with our recognition of it as 2:3:6-trimethylgalactose. Complete methylation of the trimethylgalactose yielded a galactoside which, on hydrolysis, gave tetramethylgalactopyranose [Haworth *et al.*, 1924, 1927; Pryde, 1923].

It is evident that a 2:3:6-trimethylgalactose might occur as a scission product of a polysaccharide consisting of hexo-furanose or -pyranose units. At present the behaviour of varianose towards *N*/100 and *N*/10 HCl respectively inclines us to the view that the pyranose form only is present in this polysaccharide. We are supported in this view by the circumstance that we have prepared by means of *P. Charlesii* G. Smith another polysaccharide [Haworth, Raistrick and Stacey, unpublished] which indubitably contains only galactofuranose units and its properties contrast significantly with those of varianose.

From methylated varianose we were also able to isolate about 14 % of another trimethyl-methylhexoside which probably represents the hexose residue terminating the polysaccharide chain at the end remote from that occupied by glucose. This portion yielded a liquid trimethylhexose and also a liquid trimethylhexonolactone, but the latter gave easily and quantitatively a crystalline phenylhydrazide not identical with the phenylhydrazide of any known trimethylhexonolactone. Moreover, the lactone itself was laevorotatory and gave a high laevorotatory value in equilibrium with the corresponding acid in water. Its oxidation with nitric acid yielded no mucic acid derivative and no product showing its relationship with galactose. Treatment of the ester of this oxidation product with ammonia yielded, however, *d*-dimethoxysuccinamide, a result

showing the orientation of methyl groups in positions 2 and 3 of the corresponding trimethylhexose. It therefore appears that the hexose representing the reducing end of the polysaccharide chain is either *D*-idose or *l*-altrose. The low value of the specific rotation suggests that varianose is composed largely of  $\beta$ -hexose units.

#### EXPERIMENTAL.

*Preparation of the polysaccharide* (with Dr C. G. Anderson). The mould used for the production of the polysaccharide was a new species belonging to the group *Biverticillata-symmetrica*. It was isolated from cotton in 1927 by Mr G. Smith and named by him *Penicillium varians*. It bears the L.S.H.T.M. Catalogue number A. 91. A culture has been deposited with the Centraalbureau voor Schimmelcultures, Baarn, Holland.

The mould was grown on a standard Czapek-Dox medium containing glucose as the sole source of carbon and of the following composition: glucose, 1750 g.;  $\text{NaNO}_3$ , 70 g.;  $\text{KH}_2\text{PO}_4$ , 35 g.; KCl, 17.5 g.;  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , 17.5 g.;  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ , 0.35 g.; distilled water, 35 litres.

70 litres of this medium were prepared and placed in 350 ml. quantities in 200 conical flasks of 1 litre capacity. Sterilisation was effected by steaming on each of three successive days and when cold each flask was sown with 2 ml. of a spore suspension prepared from 50 Czapek-Dox agar slopes of *P. varians*.

The flasks were incubated at 24° and the course of metabolism of the glucose was followed by the polarimeter and by the Shaffer-Hartmann iodine titration method with the following results:

Period of incubation at 24° weeks	g. of glucose in solution/100 ml.		g. of polysaccharide (crude)
	Polarimeter	Shaffer-Hartmann	
8	1.60	1.57	0.52 (1 flask)
11	0.52	0.48	0.35 (1 flask)
11½	0.78	0.71	2.46 (5 flasks)

After 12 weeks. the somewhat mucilaginous solution was filtered from the mycelium and concentrated *in vacuo* at 45–50° to 1600 ml. of a dark red syrup. 160 ml. of conc. HCl were added to this syrup and the polysaccharide was then immediately precipitated as a creamy powder by the addition of 6 litres of 95% alcohol. After an hour the clear liquid was decanted off. A little more product separated from the mother-liquor overnight. The product was isolated by centrifuging and dissolved in 1 litre of distilled water. It was precipitated as a sticky mass from this solution by the addition of 5 litres of 95% alcohol. Further purification was effected by repeated precipitations from both acid and neutral aqueous solutions by means of alcohol, until an almost ash-free compound was obtained. Trituration of the sticky mass with absolute alcohol gave the polysaccharide as a white powder which was washed with ether and dried over concentrated sulphuric acid in a vacuum desiccator; yield, 104 g. Precipitation of the polysaccharide from aqueous solution by ethyl alcohol at different concentrations of alcohol gave a series of fractions which showed no differences in rotation or other properties among themselves or from the original material, and the polysaccharide thus appeared to be homogeneous. It showed  $[\alpha]_D^{20} + 15.0^\circ$  (c, 0.894 in water). (Found (moisture, 7.33%; ash, 2.0%): C, 44.9; H, 6.6%.  $(\text{C}_6\text{H}_{10}\text{O}_5)_x$  requires C, 44.4; H, 6.2%.)

In a second experiment 100 flasks each containing 350 ml. of Czapek-Dox medium and incubated in this case at 28° for 7 weeks gave 105 g. of varianose,  $[\alpha]_D^{20} + 15.0^\circ$  (c, 0.85 in water). The aqueous-alcoholic mother-liquors remaining

after the initial precipitation of the varianose from the evaporated metabolism solution gave, on evaporation, 65 g. of *d*-mannitol.

The polysaccharide was a white amorphous powder moderately soluble in water giving a clear solution which frothed considerably on shaking. In the presence of alcohol it tended to form gummy products. It reduced Fehling's solution slightly on boiling and its aqueous solution was neutral to litmus. It gave no colour with iodine.

*Hydrolysis with N/10 HCl* was carried out at 100°. The initial rotation of +15° changed to +90° in 3 hours. Initial rotation +15.0°, +22.0° (5 min.), +48.3° (20 min.), +75.7° (50 min.), +81.9° (80 min.), +89.4° (120 min.), +90° (180 min., equilibrium value). Equilibrium rotation calculated as hexose  $[\alpha]_D + 81^\circ$ .

*Examination of the hydrolysis products.* The polysaccharide (1 g.) was heated for 3 hours at 100° with 30 ml. of *N/10* HCl. The acid was neutralised with barium carbonate, the solution filtered and evaporated to dryness under reduced pressure at 25°. The syrupy residue was extracted repeatedly with 95% alcohol which, on removal by distillation, left a viscid pale brown syrup (0.85 g.). This syrup reduced Fehling's solution very strongly.

*Formation of galactosazone from the above syrup.* The syrup (0.35 g.) was dissolved in water (2 ml.) and heated on the boiling water-bath for 15 min. with phenylhydrazine acetate (0.55 g.); the osazone which separated (0.5 g.) after recrystallisation from water and pyridine had m.p. 195°, unchanged on admixture with authentic galactosazone.

*Formation of mucic acid.* The syrupy hydrolysis product (0.3 g.) was heated with nitric acid (1.2 ml., sp. gr. 1.2) for 6 min. On dilution with water and standing, a white crystalline substance (0.28 g.) separated. This was filtered off, washed with water and dried *in vacuo* over calcium chloride. It had m.p. 214° (with decomposition) alone or in admixture with an authentic specimen of mucic acid. A sample was also prepared directly from the polysaccharide.

*Preparation of crystalline galactose from the polysaccharide.* The polysaccharide (2 g.) was hydrolysed by heating it for 30 min. with *N* HCl (100 ml.). The acid was neutralised in the cold with silver carbonate and the solution, filtered from the silver salts, was slowly evaporated at 15° leaving a colourless syrup which crystallised on nucleation with *d*-galactose. It was recrystallised from absolute alcohol. Yield, 1.4 g. (70%),  $[\alpha]_D^{20} + 140^\circ \rightarrow + 82^\circ$  (c, 1.1), equilibrium value. A residual syrup (0.5 g.) did not crystallise.

*Preparation of varianose acetate.* Varianose (1.3 g.) was dissolved in a small amount of hot water (1.5 ml.) and pyridine (25 ml.) was added. The solution was cooled in an ice-bath and acetic anhydride (25 ml.) was dropped in slowly with constant stirring, care being taken to prevent any considerable rise in temperature. After several days at 15° the reaction mixture was poured into warm water (300 ml.) which was vigorously stirred. The acetate was precipitated as a white flocculent powder. It was filtered and freed from excess pyridine and acetic acid by continuous washing with warm water for 6 hours. It was further purified and freed from traces of ash by dissolving it in hot methyl alcohol and filtering through muslin on a hot-jacketed funnel. It was reprecipitated from the alcoholic solution on cooling, filtered, washed with ether and dried in the vacuum oven over calcium chloride at 50°; yield, 2.2 g. (quantitative). It did not reduce Fehling's solution.

Varianose acetate was a finely divided white powder which had m.p. 148–155°. It dissolved readily in chloroform, acetone and hot alcohol, but these solutions could only be filtered through muslin.  $[\alpha]_D^{20}$  in chloroform, +30.0° (c, 0.95);  $[\alpha]_D^{20}$  in acetone, +38.2° (c, 0.68). (Found: C, 50.3; H, 5.6; OAc, 43.8%.  $[C_6H_7O_2(OCOCH_3)]_x$  requires C, 50.0; H, 5.6; OAc, 44.8%.) Deacetylation of

the acetate with *N* NaOH gave the original ash-free polysaccharide unchanged in properties.  $[\alpha]_D^{20} + 15.0^\circ$  (*c*, 0.96).

*Attempted fractionation of varianose acetate.* 30 g. of the acetate were made and purified in the manner described. Fractional precipitation was attempted from hot methyl alcohol, from mixtures of chloroform and alcohol, and from chloroform and light petroleum. Acetyl values and rotations were determined for each fraction but in no case could a fraction be obtained which differed in properties from the original acetate. It was concluded that the polysaccharide was homogeneous.

*Methylation of the polysaccharide.* The polysaccharide (6 g.) was dissolved in water (20 ml.) and 100 g. of KOH in 100 ml. of water added. It was methylated by the gradual addition of methyl sulphate (95 ml.) at  $15^\circ$  over a period of 5 hours. Acetone (100 ml.) was added after 1 hour. The liquid was boiled for 30 min. and poured into 1000 ml. of hot water. The methylated product formed a light brown gum on the surface of the hot water from which it was collected. Its solution in chloroform was washed with water, dried over anhydrous magnesium sulphate and evaporated. The pale yellow viscid syrup which remained was triturated with light petroleum ( $40-60^\circ$ ) yielding the methylated compound as a fine cream-coloured powder; yield, 7.5 g.; OMe, 36.2%.

One further treatment of this partially methylated product with KOH and methyl sulphate gave a fully methylated derivative (yield, 7.5 g. OMe, 45.9%). It was a white ash-free powder, insoluble in hot water but very soluble in cold water, acetone and chloroform. It was non-reducing and had m.p.  $90-100^\circ$ ;  $[\alpha]_D^{20} + 20^\circ$  (*c*, 1.10 in chloroform);  $[\alpha]_D^{20} + 23^\circ$  (*c*, 0.95 in benzene);  $[\alpha]_D^{20} + 15^\circ$  (*c*, 1.08 in water). (Found: C, 53.2; H, 8.0; OMe, 45.9%. (Moisture content 1.08%.) ( $C_6H_{16}O_6$ )<sub>*n*</sub> requires C, 52.9; H, 7.8; OMe, 45.6%.)

*Hydrolysis with boiling 3% methyl alcoholic HCl.*  $[\alpha]_D + 17.1^\circ$  (initial value);  $+10.5^\circ$  (0.25 hours);  $-8.6^\circ$  (0.75 hours);  $-13.6^\circ$  (1.75 hours, equilibrium value). (*c*, 1.05.)

#### *Hydrolysis of methylated varianose.*

30.5 g. of methylated varianose were hydrolysed by boiling gently for 5 hours with 700 ml. of boiling 3% methyl alcoholic HCl. No discoloration took place and no furfuraldehyde derivatives could be detected. The acid was neutralised with silver oxide at  $15^\circ$ . After filtration the solution was evaporated at  $35^\circ/18$  mm. to a syrup which was dissolved in dry ether to remove traces of silver salt. Evaporation gave a colourless mobile syrup. A portion of this syrup b.p.  $120-122^\circ/0.04$  mm. had the following properties:  $n_D^{18}$ , 1.4514;  $[\alpha]_D^{20} - 31.8^\circ$  (*c*, 0.96 in water). (Found: C, 50.5; H, 8.5; OMe, 53.6%.  $C_{10}H_{20}O_6$  requires C, 50.8; H, 8.5; OMe, 52.5%.)

*Hydrolysis of the mixture of methylated hexosides.* After a trial hydrolysis with 2% HCl solution at  $100^\circ$  the following values were obtained (*c*, 0.781)  $[\alpha]_D - 32.5^\circ$  (initial value);  $-2.0^\circ$  (7 min.);  $+22.0^\circ$  (20 min.);  $+44.0^\circ$  (50 min.);  $+49.2^\circ$  (80 min.);  $+53.0^\circ$  (120 min., equilibrium value). Equilibrium value calculated as trimethylhexose,  $+56^\circ$ . No furfuraldehyde derivatives were detected during hydrolysis and no discoloration took place.

*Fractionation of the mixture of methylated hexosides.* The mixture of methylated hexosides was hydrolysed by heating it (30 g.) in 300 ml. of 2% HCl at  $100^\circ$  for 5 hours. The HCl was neutralised with barium carbonate, charcoal was added and the solution filtered, the precipitate being well washed with warm water. The aqueous solution (400 ml.) was extracted 10 times with chloroform. The chloroform solution was dried over anhydrous magnesium sulphate, filtered and evaporated. A colourless fairly viscid syrup Fraction A remained (8.1 g.).

The aqueous solution was evaporated to dryness and the solid extracted 10 times with boiling chloroform. This chloroform solution was dried over magnesium sulphate, filtered and the solvent distilled off. A colourless viscid syrup Fraction B remained (21 g.).

*Fractionation of Fraction A by means of solvents.* Fraction A was dissolved in chloroform to give a thick syrup, and 200 ml. of light petroleum (40–60°) were added to this and the mixture stirred vigorously. The petroleum layer was decanted after standing and this treatment was repeated several times. Removal of the petroleum by distillation gave a highly mobile syrup  $A_1$ : yield, 4.5 g. Removal of the chloroform by distillation gave a fairly mobile syrup  $A_2$  (yield, 3.5 g.).

*Fractional distillation.* Each fraction was now treated separately and converted back into the glycoside stage by the action of boiling methyl alcoholic HCl (2 %).

*Distillation of  $A_1$ .* The highly mobile syrup (4.5 g.) was distilled in high vacuum from a Claisen flask with a wide side limb, the first fraction  $F_1$  being collected in a Widmer flask which was used as a receiver and from which it could be redistilled. In this and succeeding distillations the syrup was distilled very slowly in order to secure the best possible fractionation. In no case was there any decomposition and no furfuraldehyde derivatives could be detected. The following fractions were obtained:

$F_1$  at b.p. 90°/0.04 mm. (3.5 g. of a colourless highly mobile liquid).

$F_2$  at bath temperature 140–143°/0.04 mm. (1.0 g. of a colourless mobile syrup).

$F_1$  (3.5 g.) was now distilled from the Widmer flask fitted with a fractionating column and the following fractions were obtained:

$F_{1.1}$  at bath temperature 120–123°, b.p. 90°/0.06 mm.,  $n_D^{15}$  1.4455, 3.2 g.

$F_{1.2}$  at bath temperature 140–145°/0.06 mm.,  $n_D^{15}$  1.4519, 0.2 g.

$F_{1.1}$ , as shown below, was tetramethyl- $\alpha\beta$ -methylglucopyranoside. (Found: OMe, 60.0 %. Calc. 62.0 %.)

A portion of it (2 g.) was hydrolysed with boiling 4 % aqueous HCl in the usual manner. The product was a crystalline solid (1.9 g.) which on recrystallisation from light petroleum (b.p. 40–60°) gave, almost quantitatively, long needles of tetramethylglucopyranose; M.P. alone or in admixture with an authentic specimen 88°;  $[\alpha]_D^{25} + 84^\circ$  (c, 1.1 in water) (equilibrium value). It was further identified by formation of its crystalline anilide by the usual method.

*Further fractionation of the residues.* Fractions  $A_2$ ,  $F_{1.2}$  and  $F_2$  were mixed (4.7 g.) and distilled as before giving:

$F_3$  at bath temperature 120–130°/0.06 mm. (A colourless very mobile liquid, 1.5 g.)

$F_4$  at bath temperature 140–150°/0.06 mm. (A colourless mobile syrup, 3.0 g.,  $n_D^{15}$  1.4559.

$F_3$  (1.5 g.) was fractionated by means of the Widmer flask and column and the first fraction at bath temperature 120–125° had b.p. 90–92°/0.06 mm. and  $n_D^{15}$  1.4488; yield, 0.95 g. ( $F_{3.1}$ ). (Found: OMe, 56.5 %.)

The calculated amount of tetramethyl-methylglucopyranoside contained in  $F_{3.1}$  was 0.61 g. and the total yield of the latter from 30 g. of methylated hexosides was 3.81 g. The experimental loss from hydrolysis and fractionation as shown by Haworth and Machemer [1932] is not greater than 10 % of the weight of tetramethylglucose. Hence the total estimated yield of tetramethylglucose was 14 %

by weight of the methylated varianose (this gives a chain length of about 8 units) No tetramethylgalactose could be detected.

*Examination of the trimethyl portions.* (a) *Chloroform-soluble.* The residues from the distillations of  $F_3$  and  $F_{3-1}$  (0.8 g.) and the fraction  $F_4$  (3 g.) were mixed and distilled (3.8 g.) at bath temperature  $140-143^\circ/0.06$  mm.; yield, 3.4 g.,  $n_D^{100}$  1.4550 ( $F_4$ ). (Found: C, 50.8; H, 8.6; OMe, 50.2%.  $C_{10}H_{20}O_6$  requires C, 50.8; H, 8.5; OMe, 52.5%. This shows it to be pure trimethyl-methylhexoside.) The residue (0.4 g.) had OMe, 40.7%,  $n_D^{100}$  1.4615, and probably consisted chiefly of dimethyl-methylhexoside.

(b) *Examination of water-soluble Fraction B.* Treatment of a chloroform solution of Fraction B with light petroleum in the manner previously described and subsequent conversion into the glycosides followed by distillation failed to give a low-boiling fraction and hence it contained no tetramethylglycosidic fraction. 21 g. were distilled from a Claisen flask giving 20 g. of a product having B.P.  $135-140^\circ/0.05$  mm. and  $n_D^{100}$  1.4550. (Found: C, 50.6; H, 8.6; OMe, 50.2%.  $C_{10}H_{20}O_6$  requires C, 50.8; H, 8.5; OMe, 52.5%.) (The residue (1 g.) had OMe, 40.0% and probably consisted mainly of dimethyl-methylglycoside.)

*Hydrolysis of trimethyl-methylgalactoside.* The syrup was hydrolysed with 2% aqueous HCl at  $100^\circ$ ;  $[\alpha]_D^{20}$   $0^\circ$  (initial value),  $+14^\circ$  (5 min.),  $+46.8^\circ$  (14 min.),  $+60.0^\circ$  (35 min.),  $+70.4^\circ$  (60 min., equilibrium value). Equilibrium value calculated as trimethylgalactose is  $+75^\circ$ .

Trimethyl-methylgalactoside (8 g.) was hydrolysed by heating with 500 ml. of 2% aqueous HCl at  $100^\circ$  for 2 hours. The acid was neutralised by the addition of silver carbonate in the cold. The solution was filtered and concentrated at  $30^\circ$  to a syrup. This was extracted with ether and the ethereal solution dried over anhydrous magnesium sulphate and filtered. Removal of the ether left a colourless viscid syrup:  $[\alpha]_D^{20} +75^\circ$  (c, 0.86 in water),  $[\alpha]_D^{20} +36^\circ$  (c, 0.87 in methyl alcohol);  $n_D^{100}$  1.4660; OMe, 40.1%.

*Rate of glycoside formation of trimethylgalactose.* The syrup (0.1306 g.) was dissolved in 15 ml. of 3% methyl alcoholic HCl and boiled gently. The reaction was followed polarimetrically:  $[\alpha]_D^{20} +35.6^\circ$  (initial value),  $-6.4^\circ$  (5 min.),  $-29.3^\circ$  (10 min.),  $-27.6^\circ$  (15 min.),  $-24.7^\circ$  (20 min.),  $-24.1^\circ$  (40 min. constant value). It seemed apparent that both pyranose and furanose forms were present.

*Bromine oxidation of trimethylgalactose.* The syrup (8 g.) was dissolved in water (200 ml.) and 10 ml. of bromine added. The liquid was heated at  $40^\circ$  for 24 hours and at the end of this time reduced Fehling's solution very faintly. The excess bromine was removed by a vigorous air stream and the acid neutralised with silver carbonate. The solution was filtered, freed from excess silver by the requisite amount of 2N HCl, again filtered and evaporated *in vacuo* at  $35^\circ$  leaving a solid mass of crystals (7 g.). The crystals were extracted with ether and the solution was dried over anhydrous magnesium sulphate and filtered. The solid crystallised on concentration of the ethereal solution and was recrystallised from ether-light petroleum (B.P.  $40-60^\circ$ ) in clusters of thick rods, M.P.  $99^\circ$ ,  $[\alpha]_D -40^\circ$  (initial value) in water; it was identical with trimethyl- $\gamma$ -galactonolactone [Haworth *et al.*, 1932], which was provisionally formulated as 2:3:6-trimethyl- $\gamma$ -galactonolactone.

By treatment of the mother-liquors (0.5 g.) with phenylhydrazine, a crystalline phenylhydrazone (0.5 g.), M.P.  $175^\circ$ , was isolated. This was identical with the phenylhydrazone prepared from trimethylhexonolactone and described later.

*Amide of trimethyl- $\gamma$ -galactonolactone.* This was prepared in the usual manner by the action of concentrated ammonia on the lactone in methyl alcoholic

solution, and recrystallisation of the product from acetone gave long needles, m.p.  $135^{\circ}$ ,  $[\alpha]_{D}^{20} + 20.5^{\circ}$  (c, 0.733). (Found: C, 45.4; H, 8.0; N, 6.2; OMe, 38.7%.  $C_9H_{19}O_6N$  requires C, 45.5; H, 8.1; N, 5.9; OMe, 39.2%.)

*The structure of 2:3:6-trimethylgalactonolactone.*

The water-soluble trimethylgalactose (2.5 g.) was converted into the galactoside and redistilled twice in high vacuum at  $135^{\circ}/0.07$  mm. in order to free it from the small amount of impurity due to the trimethylhexose b.p.  $140^{\circ}/0.07$  mm.

The galactoside was hydrolysed by means of aqueous HCl and the product, trimethylgalactose (2 g.), was carefully dried by heating at  $70^{\circ}$  for 2 hours. It was dissolved in methyl iodide (15 ml.) and methylated twice by boiling gently with silver oxide (5 g.). The methylated product was isolated in the usual way and purified by ether extraction. It had b.p.  $95^{\circ}/0.05$  mm. (bath temperature  $120^{\circ}$ ); yield, 1.8 g. of a colourless mobile syrup,  $n_D^{20}$  1.4450, OMe, 60.0%.

*Hydrolysis of tetramethyl-methylgalactoside.* The syrup (1.8 g.) was dissolved in 2% aqueous hydrochloric acid (50 ml.) and heated at  $100^{\circ}$  until the rotation was constant (2 hours). The acid was neutralised with silver carbonate and the solution filtered after the addition of charcoal. The aqueous solution was concentrated at  $35^{\circ}/18$  mm. and the residual colourless syrup extracted with ether. Distillation of the ether left a colourless mobile syrup (1.6 g.) which was tetramethylgalactose;  $n_D^{18}$  1.4523,  $[\alpha]_D^{20} + 58^{\circ}$  (c, 0.963 in water), OMe, 51.5%. This rotation indicated that the tetramethylgalactose was a mixture of the pyranose and furanose forms.

*Isolation of tetramethylgalactopyranose anilide.* Tetramethylgalactose (1.5 g.) (prepared as described above) was boiled with aniline (0.6 g.) in absolute alcohol solution (50 ml.) for 5 hours. The solution was concentrated to a thick syrup which rapidly crystallised in long needles. These were readily recrystallised from hot ethyl acetate; yield, 1 g.; m.p. and mixed m.p. with an authentic specimen of tetramethylgalactopyranose anilide,  $198^{\circ}$ . The isolation of the pyranose form shows that position 5 is free in the trimethylgalactose, hence the trimethyl- $\gamma$ -galactonolactone isolated from it and described previously must be 2:3:6-trimethyl- $\gamma$ -galactonolactone.

*Investigation of the chloroform-soluble trimethylhexoside A.* As described previously analysis had shown this fraction to consist of a pure trimethyl-methylhexoside, and accordingly its hydrolysis in 2% aqueous HCl solution was followed polarimetrically;  $[\alpha]_D^{20} - 15.6^{\circ}$  (c, 0.707) (initial value),  $0^{\circ}$  (5 min.),  $+17^{\circ}$  (12 min.),  $+27^{\circ}$  (20 min.),  $+30^{\circ}$  (35 min.) (constant value). Calculated as trimethylhexose the equilibrium value is  $+31.6^{\circ}$ . The solution reduced Fehling's solution strongly.

2.2 g. of trimethyl-methylhexoside were hydrolysed and the product isolated in the usual manner; yield, 2.1 g. of a viscous colourless syrup,  $n_D^{19}$  1.4648,  $[\alpha]_D^{19} + 30.5^{\circ}$  (c, 0.852), OMe, 40.9%.

*Rate of glycoside formation of trimethylhexose.* The rate of glycoside formation of trimethylhexose with 3% methylalcoholic hydrogen chloride at  $100^{\circ}$  was followed polarimetrically;  $[\alpha]_D^{20} + 25.8^{\circ}$  (initial value),  $-21^{\circ}$  (5 min.),  $-29.1^{\circ}$  (10 min.),  $-30.7^{\circ}$  (15 min.), (equilibrium value) (c, 0.62). These rapid rates of glycoside formation and hydrolysis indicated the presence of the furanose form.

*Bromine oxidation of trimethylhexose.* The syrup (2 g.) was dissolved in water (75 ml.) and bromine (3 ml.) added. The liquid was well shaken and allowed to stand overnight at  $15^{\circ}$ . It was then heated for 12 hours at  $40^{\circ}$ ; oxidation was then complete. The excess bromine was removed by a vigorous air stream and the lactone isolated in the usual manner; yield, 1.8 g. of a clear syrup,  $n_D^{18}$  1.4665.

On nucleation with 2:3:6-trimethyl- $\gamma$ -galactonolactone the syrup crystallised partially. Ether was added and the crystals filtered off; yield, 0.2 g. (11%); m.p. and mixed m.p. with 2:3:6-trimethyl- $\gamma$ -galactonolactone, 99°.

Nothing further would crystallise and the residual syrup (1.5 g.) was treated with phenylhydrazine (0.7 g.) in dry ethereal solution. There was an immediate precipitate and on boiling off the ether a white crystalline mass remained. It was washed with dry ether and crystallised from hot ethyl acetate in the form of fine white needles, m.p. 175°. (Found: C, 54.8; H, 7.6; N, 8.5; OMe, 27.4%. The phenylhydrazone of a trimethylhexonolactone  $C_{15}H_{24}O_6N_2$  requires C, 54.8; H, 7.4; N, 8.5; OMe, 28.4%.)

*Regeneration of pure trimethyl hexonolactone.* The phenylhydrazone (2.1 g.) was boiled with the equivalent of *N* HCl for 2 hours. The solution was evaporated to dryness *in vacuo* and the residue extracted repeatedly with ether containing a little chloroform. Evaporation gave a brown syrup which distilled at bath temperature 138–140°/0.04 mm. (B.P. 110–115°) giving 1.4 g. of a pale yellow mobile syrup,  $n_D^{16}$  1.4628. The syrup immediately gave, with phenylhydrazine, a theoretical yield of the phenylhydrazone, m.p. 175°, described above. (Found: OMe, 41.6.  $C_6H_{16}O_6$  requires OMe, 42.3%.) 0.0759 g. required 3.7 ml. *N*/10 NaOH (theory requires 3.5 ml.);  $[\alpha]_D^{20}$  –62.4° (c, 0.99).

*Hydrolysis in aqueous solution* (c, 0.99).  $[\alpha]_D^{20}$  –62.4° (initial value); –60.4° (1 day); –49.8° (3 days); –44.7° (5 days); –44.1° (8 days); –43.0° (12 days); –42.4° (18 days; equilibrium value). It is therefore a  $\gamma$ -lactone.

The rotation of acid  $\rightarrow$  lactone was determined in the usual manner (c, 1.15).  $[\alpha]_D^{20}$  –27.8° (initial value as lactone); –37.2° (4 days); –44.1° (9 days); –44.1° (15 days). The proportions of lactone and acid at equilibrium are 55% and 45% respectively.

*Nitric acid oxidation of trimethylhexono- $\gamma$ -lactone.* The lactone (0.8 g.) purified by regeneration from the phenylhydrazone was heated at 60° for 6 hours with nitric acid (6 ml., sp. gr. 1.2). The excess nitric acid was removed by distillation with the continuous addition of water for 6 hours. The product was dried by heating at 100° for 1 hour and was then esterified in the usual manner by boiling with 4% methyl alcoholic HCl. It was distilled (0.45 g.) in vacuum giving:

Fraction I. B.P. 80–100°/18 mm., 0.1 g. of a highly mobile liquid,  $n_D^{16}$  1.4268.

Fraction II. B.P. 100–110°/18 mm., 0.3 g. of a mobile liquid,  $n_D^{16}$  1.4325.

On treatment with methyl alcoholic ammonia Fraction I yielded 0.07 g. of oxamide immediately and thus consisted chiefly of methyl oxalate. Fraction II yielded 0.04 g. of oxamide which was filtered off. The remainder of the solution after standing for 2 days deposited crystals in the form of clusters of thick rods with pointed ends; yield, 0.25 g., m.p. 284° (decomp.),  $[\alpha]_D^{20}$  +93°. The amide is *d*-dimethoxysuccinamide and its isolation shows that positions 2 and 3 are methylated in the trimethyl- $\gamma$ -hexonolactone. No methylated mucic acid derivative and no trimethoxyglutaramide could be detected.

*Methylation of trimethyl- $\gamma$ -hexonolactone.* The lactone (1 g.) was methylated twice with Purdie's reagents and the product distilled at bath temperature 140–145°/0.02 mm. It had  $n_D^{16}$  1.4590;  $[\alpha]_D^{20}$  +10.6° (unchanged after several days). 0.0774 g. required 3.0 ml. of *N*/10 NaOH (theory requires 3.3 ml.). (Found: OMe, 50.2%. Tetramethylhexonolactone requires OMe 53.0%.)

The methylated compound was methylated again with silver oxide and methyl iodide and distilled. The product distilled at bath temperature 140–143°/0.05 mm., and had  $n_D^{16}$  1.4610. It did not form a crystalline amide or a stable phenylhydrazone and the conclusion was reached that the trimethylhexono-

lactone was unstable to methylation with silver oxide and methyl iodide. This behaviour is different from that of trimethyl- $\gamma$ -galactonolactone.

*Methylation of trimethylhexose. F<sub>4</sub>.* A portion of the trimethyl-methylhexoside F<sub>4</sub> was redistilled several times in order to free it from the small amount of trimethyl-methylgalactoside and the fraction (0.6 g.) distilling at bath temperature 143°/0.06 mm. was retained.

This syrup was hydrolysed with 1.5% aqueous HCl to give trimethylhexose (0.5 g.), which was methylated twice with methyl iodide (10 ml.) and silver oxide (4 g.). The product was a colourless and very mobile liquid which had B.P. 90–95°/0.03 mm.,  $n_D^{20}$  1.4448 and  $[\alpha]_D^{20}$  +25.2° (c, 1.86 in water). (Found: OMe, 61.6. Tetramethyl-methylhexoside requires OMe, 62.0%.)

*Hydrolysis with 0.4% aqueous HCl at 100°.*  $[\alpha]_D^{20}$  +25.4° (initial value): +22.7° (5 min.): +21.7° (15 min.): +21.5° (40 min.; equilibrium value). The remainder (0.45 g.) was hydrolysed to give (0.4 g.) of a mobile, colourless and strongly reducing syrup. This syrup was dissolved in water (10 ml.) and bromine (0.25 g.) added. The temperature was maintained at 40° for 24 hours; oxidation was then complete. The lactone was isolated in the usual way. Yield, 0.12 g.;  $n_D^{20}$  1.4500. (Found: OMe, 51.1. C<sub>10</sub>H<sub>18</sub>O<sub>6</sub> requires OMe, 53%.)

*Hydrolysis of the above tetramethylhexonolactone in aqueous solution.*  $[\alpha]_D^{20}$  +31.5° (initial value) (c, 0.923); +20.2° (30 hours): +15.2° (48 hours): +13.0° (90 hours; equilibrium value).

A phenylhydrazide of the above lactone was prepared. It was a white microcrystalline powder with m.p. 172° but was unstable in moist air. The yield was 36% but there was insufficient material for analysis.

From its behaviour on methylation and from the fact that the trimethylhexono- $\gamma$ -lactone derived from it gives only *d*-dimethoxysuccinic acid on oxidation it is concluded that the unknown trimethylhexose is a derivative of either *d*-idose or *l*-altrose.

#### *Molecular size of the polysaccharide.*

It has been shown by the isolation of 14% of tetramethylglucose from one end of the chain in the methylated polysaccharide that the polysaccharide itself is a long-extended molecule consisting of 8–10 mutually linked hexose units. This value has been confirmed by the estimation of iodine numbers and by determining the mol. wt. of the methylated polysaccharide by Rast's method. Mean mol. wt. of methylated polysaccharide 1622. (C<sub>9</sub>H<sub>16</sub>O<sub>5</sub>)<sub>8</sub> requires mol. wt. 1632. The iodine numbers of the polysaccharide and of its acetate were determined by the method of Bergmann and Machemer [1930]. Iodine number of the polysaccharide 14 (corresponding to about 9 hexose units). Iodine number of the acetate 8 (corresponding to about 9 acetylhexose units).

#### SUMMARY.

The molecular structure of varianose, a hitherto undescribed polysaccharide produced from glucose by *Penicillium varians* G. Smith, has been investigated. On acid hydrolysis varianose gives a mixture of *d*-glucose, *d*-galactose and a third hexose which is either *l*-altrose or *d*-idose. Varianose forms acetyl and methyl derivatives which are essentially homogeneous. On treatment with methyl alcoholic HCl the methyl derivative gives a mixture of 14% 2:3:4:6-tetramethyl-methylglucopyranoside, 70% of 2:3:6-trimethyl-methylgalactoside and 14% of a trimethyl-methylhexoside which was identified as a derivative of either *l*-altrose or *d*-idose. From consideration of these hydrolysis products and

from molecular weight determinations, it is shown that varianose is constituted of a chain of 6-8  $\beta$ -galactopyranose units with a glucopyranose unit at one end of the chain and a unit of either *l*-altrose or *d*-idose at the reducing end. Proof of the structure of 2:3:6-trimethylgalactofuranolactone is given.

# CCCXVII. METABOLISM OF POLYCYCLIC COMPOUNDS.

## I. PRODUCTION OF DIHYDROXYDIHYDRO-ANTHRACENE FROM ANTHRACENE.

BY ERIC BOYLAND AND ALFRED AARON LEVI.

*From the Research Institute of The Cancer Hospital (Free), London, S.W. 3.*

*(Received October 2nd, 1935.)*

POLYCYCLIC aromatic hydrocarbons are known to produce two distinct pathological changes in animals. Thus under certain conditions naphthalene produces cataract in rabbits, whilst under other conditions derivatives of 1:2-benzanthracene produce cancer in some species. It is possible that animals might deal with toxic hydrocarbons in either of two ways; the compounds might either be converted into more active pathogenic substances or be detoxicated by conversion into some harmless compound. Our present knowledge of the metabolism of aromatic hydrocarbons with the exception of benzene and naphthalene is very scanty.

It has been known for some time that the urine of naphthalene-fed animals liberates naphthalene on boiling with acid [Baumann and Heuter, 1878]. Bourne and Young [1934] have isolated naphthalenemercapturic acid from the urine of naphthalene-fed rabbits. Bergel and Pschorr [1903] isolated phenanthrolyglycuronic acid from the urine of rabbits which had been given phenanthrene in their food, but they were unable to determine the constitution of this glycuronic acid compound.

### EXPERIMENTAL.

The rats and rabbits received the following diet:

	Parts		Parts
Wholemeal flour	30	Wheat germ	18
Dried milk powder	10	Bran	18
Lard	16	Dried yeast	2
NaCl	2	Anthracene	4

Both rats and rabbits were given milk and a small amount of fresh green food and of cod-liver oil mixed in the diet each day. The animals were kept in metabolism cages of the Paine type and the pooled urine of each species was collected.

*Isolation of products from urine.* The urine was filtered through kieselguhr before any process of separation was carried out. The filtered urine from rats and rabbits gave crystalline anthracene on boiling with dilute acid. The precursor of this anthracene has not yet been isolated.

Precipitation of the urine with lead acetate and barium acetate did not yield any pure material although the urine of both species gave a positive naphthoresorcinol test for glycuronic acid, and conjugated glycuronic acids have often been isolated by means of their lead salts.

The filtered urine was extracted with ether in continuous extractors for 1, 2 or 3 days. The ether extract of this untreated urine was washed with NaOH solution and water, dried and evaporated. The brown crystalline residue was recrystallised from toluene. Products with similar chemical behaviour were

isolated from both rat and rabbit urine in yields up to 100 mg. per litre of urine. This corresponds to a yield of about 0.5% of the anthracene consumed.

*Product isolated from the neutral ether extract of urine of rats.* The substance from rat urine crystallised in white prisms, M.P. 160–161°, with previous decomposition;  $[\alpha]_D^{25}$  in acetone—154° (c, 1), in dioxan—100° (c, 2). It was soluble in ether, alcohol and acetone, and moderately soluble in hot water and hot benzene. The solutions had a faint blue fluorescence. (Analysis (Schoeller). Found: C, 78.9; H, 5.5%; mol. wt. 227, 222.  $C_{14}H_{12}O_2$  requires C, 79.2; H, 5.6%; mol. wt. 212.)

The substance was not soluble in ammonia or NaOH, hence it was not phenolic. It was acetylated with boiling acetic anhydride containing pyridine for 15 min. (without pyridine the substance was recovered unchanged after a short boiling in acetic anhydride). The diacetate (III) separated on addition of water and was recrystallised from light petroleum, M.P. 149°;  $[\alpha]_D^{20}$  (c, 0.05) in benzene—375.5°; in dioxan—362° (c, 1). Insoluble in water, soluble in organic solvents with violet fluorescence. (Found (Schoeller): C, 72.9; H, 5.4%.  $C_{18}H_{16}O_4$  requires C, 73.0; H, 5.4%.)

The analyses thus agree with the formula for a dihydroxydihydroanthracene (I) or (II). The optical activity indicates that the carbon atoms bearing the OH groups are the reduced ones.

Boiling the substance with dilute acid produced  $\alpha$ -anthrol (IV), M.P. 149–151° (M.P. of  $\alpha$ -anthrol 150–153° [Dienel, 1905]), which was soluble in alkali with a yellow colour and oxidised in air to give a blue colour and precipitate. The benzene solution had a strong blue-violet fluorescence. (Found (Schoeller): C, 86.2; H, 5.3%.  $C_{14}H_{10}O$  requires C, 86.5; H, 5.2%.)

Acetylation of this with acetic anhydride in the presence of pyridine gave  $\alpha$ -acetoxy-anthracene, M.P. 128–130° (M.P. of  $\alpha$ -acetoxyanthracene 128–130° [Dienel, 1905]).

The dihydroxydihydroanthracene reacted with benzoyl chloride in pyridine. Recrystallisation of the dibenzoate from alcohol gave a product M.P. 138°;  $[\alpha]_D -452$  (c, 2). (Found (Weiler): C, 80.1; H, 5.0%.  $C_{28}H_{20}O_4$  requires C, 80.0; H, 4.7%.)

The dihydroxydihydroanthracene rapidly reduced  $\text{KMnO}_4$  in acetone with production of heat. After dilution with water and treatment with  $\text{SO}_2$  the product was extracted with ethyl acetate, and the acidic product was removed with  $\text{NaHCO}_3$  and recrystallised from hot water. It had m.p.  $242\text{--}243^\circ$  with a neutralising equivalent of 106 in agreement with that of naphthalene-2:3-dicarboxylic acid (V). (Theoretical equivalent = 108.) (Found (Schoeller): C, 66.8; H, 4.0%.  $\text{C}_{12}\text{H}_8\text{O}_4$  requires C, 66.6; H, 3.7%.)

The acid was sublimed and gave an anhydride, m.p.  $246^\circ$ , mixed m.p. with an authentic specimen  $246^\circ$ .

The dihydroxydihydroanthracene was hydrogenated by shaking the acetone solution with palladium in the presence of  $\text{H}_2$ . With a suitable catalyst ( $\text{Pd-BaSO}_4$ ) the substance took up approximately 1 mol. of  $\text{H}_2$ . The reduced product did not give  $\alpha$ -anthrol on boiling with acid and was more soluble in water and benzene than the original substance. The solutions of the reduction product showed no fluorescence. It crystallised in plates, m.p.  $149^\circ$ , from benzene and appeared to be dihydroxytetrahydroanthracene (VI):  $[\alpha]_D^{20}$  in dioxan  $+99^\circ$  (c, 2). (Found (Schoeller): C, 78.5; H, 6.6%.  $\text{C}_{14}\text{H}_{14}\text{O}_2$  requires C, 78.5; H, 6.5%.)

This dihydroxytetrahydroanthracene was acetylated by boiling with acetic anhydride in the presence of a little pyridine. The acetate crystallised from aqueous acetic acid in plates, m.p.  $91^\circ$ ;  $[\alpha]_D^{20}$  in dioxan  $-74^\circ$  (c, 1). (Found (Weiler): C, 72.7; H, 6.2%.  $\text{C}_{18}\text{H}_{18}\text{O}_4$  requires C, 72.5; H, 6.4%.)

The dihydroxytetrahydroanthracene was warmed with  $\text{KMnO}_4$  in acetone for a few minutes. An acid was isolated which crystallised from hot water in laminae, m.p.  $210^\circ$ , with slight decomposition. The neutralisation equivalent (120) agrees with that of naphthalene-2-carboxy-3-propionic acid (VII). Theoretical equivalent = 123. (Found (Schoeller): C, 68.8; H, 4.9%.  $\text{C}_{14}\text{H}_{14}\text{O}_4$  requires C, 68.8; H, 4.9%.)

The dihydroxytetrahydroanthracene and the diacetate of this compound on boiling with acid yielded a pink crystalline substance, insoluble in alkali, optically inactive and of m.p.  $149^\circ$ . (Found (Weiler): C, 85.3; H, 6.3%.  $\text{C}_{14}\text{H}_{12}\text{O}$  requires C, 85.5; H, 6.1%.)

This substance reacted with phenylhydrazine and appeared to be either 1- or 2-ketotetrahydroanthracene. Braun and Bayer [1929] have described 1-ketotetrahydroanthracene, melting at  $95^\circ$ , and 2-ketotetrahydroanthracene melting at  $148\text{--}150^\circ$ . The substance obtained by acid hydrolysis is therefore probably 2-ketotetrahydroanthracene (VIII).

The analytical figures and behaviour on acetylation show that the ether-soluble substance contains two hydroxyl groups and, as it yields  $\alpha$ -anthrol on acid hydrolysis, one of the OH groups is in the  $\alpha$ -position of the anthracene nucleus. It might therefore be either 1:4-dihydroxy-1:4-dihydroanthracene (I) or 1:2-dihydroxy-1:2-dihydroanthracene (II). It cannot be one of the meso-substituted compounds because the substance can be oxidised to naphthalenedicarboxylic acid (V) and takes up hydrogen in the presence of palladium.

Since acid hydrolysis of the dihydroxydihydroanthracene yields  $\alpha$ -anthrol and hydrolysis of the dihydroxytetrahydroanthracene gives 1-ketotetrahydroanthracene it is very probable that the dihydro-compound is 1:2-dihydroxydihydroanthracene (II).

The  $\text{KMnO}_4$  oxidation of 1:4-dihydroxy-1:2:3:4-tetrahydroanthracene would give 1:4-diketotetrahydroanthracene or naphthalene-2:3-dicarboxylic acid, whereas 1:2-dihydroxy-1:2:3:4-tetrahydroanthracene would give naphthalene-2-carboxy-3-propionic acid. The isolation of what is apparently naphthalene-2-

carboxylic-3-propionic acid (VII), an acid containing two carbon atoms more than naphthalene-2:3-dicarboxylic acid (V), by oxidation of the hydrogenated ether extract shows the neutral ether-soluble substance to be 1:2-dihydroxy-1:2-dihydroanthracene (II); the acid would accordingly be naphthalene-2-carboxy-3-propionic acid (VII).

*Substance obtained from neutral ether extract of urine of rabbits.*

This crystallised from benzene in plates, M.P. 184°, with previous decomposition:  $[\alpha]_D$  in dioxan +16° (c, 1).

It dissolved in ether, acetone, alcohol, hot water and hot benzene to give slightly fluorescent solutions. (Found (Weiler): C, 79.1; H, 5.6%.  $C_{14}H_{12}O_2$  requires C, 79.2; H, 5.7%.)

In its chemical properties it resembled the product isolated from rat urine. Acetylation with acetic anhydride and pyridine gave a diacetate, laminae, M.P. 184° from light petroleum:  $[\alpha]_D$  in dioxan +309° (c, 2). (Found (Schoeller): C, 73.0; H, 5.4%.  $C_{18}H_{16}O_4$  requires C, 73.0; H, 5.4%.) Acid hydrolysis gave an impure anthrol which gave an acetate, M.P. 129°, after recrystallisation ( $\alpha$ -acetoxyanthracene, M.P. 128–130° [Dienel, 1905].)

Oxidation with  $KMnO_4$  yielded naphthalene-2:3-dicarboxylic acid, M.P. 242–243°, identical with that obtained under similar conditions from the ether-soluble product of the rat urine. (Found: C, 66.0; H, 4.0%.  $C_{12}H_{10}O_4$  requires C, 66.6; H, 3.7%.) Hydrogenation with hydrogen and palladium gave a dihydroxytetrahydroanthracene, M.P. 162;  $[\alpha]_D^{20} - 1^\circ$  (c, 2). (Found (Weiler): C, 78.6; H, 6.76%.  $C_{14}H_{14}O_2$  requires C, 78.6; H, 6.6%.) The dihydroxytetrahydroanthracene on acetylation with boiling acetic anhydride and pyridine gave a diacetate, M.P. 84°;  $[\alpha]_D^{20} - 3^\circ$  (c, 1). (Found (Weiler): C, 72.2; H, 6.4%.  $C_{18}H_{18}O_4$  requires C, 72.5; H, 6.4%.)

The rotations of the dihydroxytetrahydroanthracene and the diacetoxytetrahydroanthracene were too small for accurate determinations with the amounts of material available. They both appeared to be slightly laevorotatory.

Oxidation of this dihydroxytetrahydroanthracene with  $KMnO_4$  in acetone gave naphthalene-2-carboxy-3-propionic acid, M.P. 205°, identical with that obtained from the rat urine under similar conditions. (Found (Weiler): C, 68.5; H, 5.2%.  $C_{14}H_{12}O_4$  requires C, 68.8; H, 4.9%.) The tetrahydro-compound on boiling with dilute HCl gave 2-keto-1:2:3:4-tetrahydroanthracene, M.P. 145–149°.

The chemical properties and composition of the derivatives of the compound from the rabbit are identical with those of the compound from the rat and the substance must therefore be 1:2-dihydroxy-1:2-dihydroanthracene. The differences in M.P. and optical rotation (Table I) show that the two species produce

Table I. *Properties of the 1:2-dihydroxy-1:2-dihydroanthracenes isolated from rat and rabbit urine.*

	Rat	Rabbit
M.P.	160–161°	184°
$[\alpha]_D^{20}$ in dioxan	-100°	+16.2°
M.P. of diacetate	149°	184°
$[\alpha]_D^{20}$ of diacetate in dioxan	-302°	+309°
M.P. of hydrogenated product	149°	162°
$[\alpha]_D^{20}$ of hydrogenated product	+98°	-1°
M.P. of diacetate of hydrogenated product	91°	84°
$[\alpha]_D^{20}$ of diacetate of hydrogenated product	-74°	-3°

different stereoisomerides of the compound. As the molecule is not symmetrical about the two asymmetric carbon atoms, internal compensation is impossible, thus four stereoisomerides of substance (II) are possible. It is not definitely proved that the substances isolated were optically pure.

As the 1:2-dihydro-1:2-dihydroxyanthracene yields  $\alpha$ -anthrol readily on acid hydrolysis and the original urine from rats gives anthracene under similar conditions it seems probable that rats excrete 1- (or 2)-hydroxy-1:2-dihydroanthracene in addition to the dihydroxy-compound. It is uncertain whether this is excreted as such or conjugated with glycuronic acid.

It is remarkable that anthracene should be attacked in the side rings in the animal body. Most chemical reactions such as halogenation, nitration or oxidation carried out *in vitro* lead to products with substituents in the 9:10 positions. It is possible that the substances isolated are formed in the gut by the action of intestinal bacteria, but if this were the case it would be very remarkable for the flora of the rat and rabbit to produce different stereoisomerides.

In addition to the two isomeric dihydroxydihydroanthracenes, two distinct glycuronic acid derivatives of anthracene have been isolated from the two species but the constitution of these has not yet been determined. Indications have also been obtained that some anthracene is excreted in the form of mercapturic acid but so far this has not been obtained in a pure condition.

Experiment in which the carcinogenic hydrocarbon 1:2:5:6-dibenzanthracene was fed to rats have led to the isolation of a substance analogous to those described in this paper. Work on its properties is now in hand.

#### SUMMARY.

Rats and rabbits fed on the same diet containing anthracene excrete different stereoisomerides of 1:2-dihydroxy-1:2-dihydroanthracene. The form excreted by rats is laevorotatory while that excreted by rabbits is dextrorotatory.

One of us (A. A. L.) has pleasure in thanking the Sir Halley Stewart Trust for a fellowship held during the progress of this work.

# CCCXVIII. THE PREPARATION OF ORNITHINE, ORNITHURIC ACID AND $\alpha$ -BENZOYLORNITHINE.

By WILLIAM ROBERT BOON AND WILLIAM ROBSON.

*From the Department of Physiology, University of London King's College.*

*(Received October 3rd, 1935.)*

AN investigation contemplated in this laboratory involved the preparation of ornithuric acid and its derivative  $\alpha$ -benzoylornithine in large amounts. The poor yields obtained by the existing methods and their tedious character made it desirable to improve these methods. Success has attended our efforts in this direction and it is thought that our results may be of value to other workers requiring these compounds and their derivatives.

The method to be described is essentially the same as those already published and consists of the following steps: arginine (or carbamido-arginine)  $\rightarrow$  ornithine  $\rightarrow$  ornithuric acid  $\rightarrow$  benzoylornithine. Ornithine can be obtained either synthetically or by the hydrolysis of arginine, and of these alternatives the latter appeared to us the more promising, especially as arginine monohydrochloride can be fairly readily isolated from a gelatin hydrolysate [Cox, 1928; Felix and Dirr, 1928]. In later experiments the lengthy preparation of arginine monohydrochloride was avoided by substituting for it the carbamido-arginine described by us [1935] in a previous paper.

The first workers to prepare ornithine in any quantity from arginine were Schulze and Winterstein [1898]. Their method consisted essentially of the hydrolysis of an arginine salt with baryta and the isolation of the ornithine so produced in the form of its dibenzoyl derivative ornithuric acid. The method has two disadvantages. The yield of ornithuric acid is only 27 % of that demanded by theory; moreover, its subsequent hydrolysis and the isolation of the ornithine are by no means easy, so that the yield of the latter compound suffers accordingly.

Bergmann and Zervas [1926] overcame the second of these difficulties by preliminary isolation of the ornithine as a salicylidene derivative of the barium salt, a compound which is practically insoluble in cold water and is readily decomposed by dilute acids. By this method they were able to obtain a 23 % yield of ornithine dihydrochloride.

Bergmann and Zervas suggested that the greatest loss occurred during hydrolysis of the arginine salt with baryta. At first sight this seems justified, especially since ornithine can be converted quantitatively into ornithuric acid. It is very unlikely that any appreciable decomposition of the ornithine occurs since Van Slyke [1911] and Plimmer [1916] showed that the amount of ammonia evolved on boiling an arginine salt with caustic alkali is always less than that required by theory if all the urea produced in the reaction were completely hydrolysed. Plimmer, in fact, showed that the amount of ammonia evolved only approached the theoretical figure if all the urea were completely hydrolysed, and that this took place only when the concentration of sodium hydroxide was greater than 20 % and the time of boiling several hours.

Another possible source of loss is suggested by the observation of Baumann and Hoppe-Seyler [1874] that when glycine is boiled with urea and baryta, ammonia is evolved and carbamidoacetic acid (hydantoic acid) is produced. Lippich [1906]

showed that this reaction was not confined to glycine by preparing  $\alpha$ -carbamido-isohexanoic acid from leucine. Later, this author [1908] showed that the reaction was applicable to most of the monoamino-acids obtainable by the hydrolysis of proteins and also to such aromatic amino-acids as anthranilic acid and sulphanilic acid. It appeared to us therefore that the urea produced in the initial stages of the reaction might react with the constituents of the mixture to give one or more of the following products:

Compound (1) is already known to us as carbamido-arginine; compound (3) is citrulline [Koga and Odake, 1914; Wada, 1930] and is characterised by an extremely insoluble copper salt. Compounds represented by the formulae (2) and (4) are as yet unknown, but their existence is possible, especially in view of the fact that Hoppe-Seyler [1933] has isolated  $\delta$ -carbamido-*n*-butylhydantoin from the urine of a cystinuric, it being formed presumably from the lysine and urea contained therein.

Examination of the reaction mixture, however, after hydrolysis of the arginine under the conditions specified either by Schulze and Winterstein or by Bergmann and Zervas, failed to reveal the presence of either carbamido-arginine or of citrulline. Nevertheless, we are not prepared to state that either of these substances or their derivatives are not present in the mixture.

The problem of the decomposition of arginine by alkali was then examined from another angle. Any change in the conditions which would lead to increased hydrolysis of the urea produced in the reaction should lead to an increased yield of ornithine. Examination of the quantity of baryta used by Schulze and Winterstein and by Bergmann and Zervas shows that the actual concentration of baryta available for hydrolysis is extremely small after allowance has been made for the amount used in liberating the arginine from its salt and the formation of the barium salt of arginine.

Comparing the amounts of free alkali present with those employed by Werner [1923] in his studies of the decomposition of urea by alkali, we arrived at the conclusion that this is where the difficulty lay. In point of fact there can be no appreciable hydrolysis of the urea produced when Bergmann and Zervas's quantities are employed since there is practically no barium carbonate precipitated during the reaction.

In order to see if the yield of ornithuric acid were increased with increasing hydrolysis of urea, we undertook a series of semi-quantitative experiments in which the amounts of ammonia evolved and of ornithine produced, isolated as ornithuric acid, were studied in relation to the time of boiling and the concentration of baryta employed. It was found that up to a certain concentration of baryta, the amounts of ammonia evolved and of ornithuric acid isolated were

increased. From an examination of the curves of Fig. 1 which represent the amount of ammonia evolved plotted against time, it will be seen that the slope of curves I and II remains approximately constant, that of III changes slightly, whilst in the case of IV the change is so marked that the total amount of ammonia evolved in the course of the reaction is less than that corresponding to III. This decrease is paralleled by the yield of ornithuric acid.

The observation that increase in the concentration of baryta employed beyond a certain optimum value produced a decrease in the yields of both ammonia and ornithuric acid, suggested that the large amount of barium carbonate produced under these conditions was causing an appreciable loss by absorption of the reactants. This idea seemed to be borne out by the fact that prolonging the time of boiling to 24 hours had no appreciable effect on the yield in case IV, whilst in the other cases the increase though small was definite. To overcome this difficulty caused by the formation of a precipitate during the course of the reaction, sodium hydroxide was substituted for barium hydroxide as the hydrolysing agent. We had a precedent for so

Fig. 1.

doing in the observations of Van Slyke [1911] and Plimmer [1916], already referred to above. It was found that on heating an arginine salt or the carbamido-compound with ten times its weight of 20 % NaOH for 6 hours a 70 % yield was obtained, whilst if the time of boiling was extended to 15 hours the yield of ornithuric acid obtained was theoretical. The modification can also be used for the isolation of ornithine salts if the hydrolysate is first acidified in order to remove carbonate, then treated with an excess of baryta and finally shaken with salicylaldehyde, according to the procedure of Bergmann and Zervas.

For the preparation of benzoylornithine from ornithuric acid two methods, essentially the same, are available in the literature. The first due to Sørensen *et al.* [1912] involves the repeated hydrolysis of ornithuric acid with successive quantities of dilute baryta on the water-bath and the recovery of the unchanged ornithuric acid. The yield is good (60 %) but the very large number of operations makes the process laborious and time-consuming. The second method, due to Wada [1930], is essentially the same but involves only one operation, boiling under reflux with baryta. His yield however drops to only 41 %. There appears to be an anomaly in this paper in so far as the quantity of baryta employed is less than that required to dissolve all the ornithuric acid. By employing a slight excess of baryta over that required to form the barium salt of ornithuric acid and of the benzoic acid produced during the course of hydrolysis, and by increasing the duration of refluxing the mixture, we have succeeded in one simple operation in obtaining a 76 % yield of  $\alpha$ -benzoylornithine of excellent purity.

## EXPERIMENTAL.

*Semi-quantitative examination of the decomposition of arginine by various concentrations of baryta solution.*

The apparatus consisted of a 150 ml. round-bottomed flask, fitted with a reflux condenser and so arranged that a stream of washed air could be drawn through into a bubbling tube containing standard acid.

2.75 g. of arginine hydrochloride were taken for each experiment, the baryta and water added and the whole boiled over a small flame with a continuous stream of ammonia-free air passing through the apparatus. At intervals the tube containing the standard acid was removed and another substituted; the excess acid being titrated against standard NaOH. After 6 hours NaOH was added to the reaction mixture in moderate excess of that required to liberate the barium from its salts and the solution while still hot was saturated with carbon dioxide and filtered. The precipitated barium carbonate was repeatedly boiled out with water and the washings saturated with carbon dioxide and filtered. The combined washings and filtrate were then made more strongly alkaline with NaOH and treated with benzoyl chloride as described by Schulze and Winterstein. The mixture was acidified to Congo red with HCl and filtered. The precipitate was washed on the filter with water, twice with cold alcohol and finally with ether until the washings were free from benzoic acid. The product had m.p. 187°, unchanged after recrystallisation from 50% alcohol. The benzoic acid was removed as described, in preference to boiling it out with water, as this procedure sometimes gave a sticky product.

The following table shows the yield of ornithuric acid obtained, corresponding to the concentration of baryta used:

Time of boiling in hours	Ba(OH) <sub>2</sub> , 8H <sub>2</sub> O/water	Yield %
6	5.15	33.2
6	10.20	51
6	20.40	57
6	20.30	54.5
17	20.40	68.5

*Preparation of carbamido-arginine from gelatin.*

Gelatin (1 kg.) was boiled with 20% HCl (2 l.) for 14 hours. The hydrolysate was evaporated *in vacuo* to a thick syrup, which was then dissolved in water and the volume made up to 4 l. 40% NaOH was added until the solution was just acid to Congo red. It was then decolorised with charcoal in the usual way. To the hot filtrate was added a hot solution of flavianic acid (200 g.) in water (1 l.) and the whole allowed to cool overnight. The precipitate was collected at the pump and repeatedly washed with cold water until the washings were free from chloride. The solid was dried, heated on the water-bath with conc. HCl (200 ml. per 100 g. of flavianate) for 2 hours, cooled overnight in the ice-chest and filtered. The solid remaining was repeatedly washed with conc. HCl until the washings were practically colourless. The filtrate and washings were combined and evaporated *in vacuo* to a thick syrup. This was dissolved in water (1 l.), the solution neutralised to litmus and the neutral solution decolorised with charcoal. The practically colourless filtrate was then treated with a solution of potassium cyanate (70 g.) in water and the whole heated on a steam-bath for an hour. On cooling the carbamido-arginine separated. It weighed 82 g., and was pure enough for the next experiment.

*Ornithuric acid from carbamido-arginine.*

Carbamido-arginine (40 g.) and 20 % NaOH (400 ml.) were heated under reflux for 15 hours. After partial neutralisation of the alkali the solution was treated with benzoyl chloride in the usual way and the product worked up as described above. The yield was 57.5 g., approximately theoretical.

*Ornithine hydrochloride from carbamido-arginine.*

Carbamido-arginine was hydrolysed as in the previous experiment, the solution being finally acidified to remove carbonate and then treated with a large excess of baryta. It was then shaken with salicylaldehyde, as described by Bergmann and Zervas. The barium salt of the salicylidene compound which separated was collected, washed with cold water and decomposed by dilute HCl. The mixture was cooled, extracted with ether, the aqueous solution evaporated to dryness *in vacuo*, the residue extracted with hot methyl alcohol and the alcoholic extract concentrated to a syrup. The residue was dissolved in water, neutralised to litmus with ammonia and concentrated. To the resulting syrup rectified spirit was added, according to the method of Jaffé [1877], until it became cloudy. On standing for several days the ornithine monohydrochloride separated as a colourless crystalline mass. This was collected at the pump and air-dried. The yield was approximately theoretical.

*Benzoylornithine from ornithuric acid.*

Sørensen *et al.* [1912] found it necessary, in carrying out this operation, to use a silver-lined flask in order to obtain an ash-free product. We found a pyrex flask suitable for the purpose. Ornithuric acid (48 g.), baryta (45 g.) and water (750 ml.) were boiled under reflux with exclusion of carbon dioxide for 15 hours. While the solution was still hot, the barium was quantitatively removed by the addition of sulphuric acid. The precipitated barium sulphate was removed from the solution and repeatedly boiled out with water. The combined filtrates were evaporated under reduced pressure to about 200 ml. and extracted with ether to remove the benzoic acid. The solution was then concentrated to a stiff syrup and treated with absolute alcohol. The white crystalline precipitate which separated was filtered off and air-dried. The product was ash-free, and when heated in the manner described by Sørensen *et al.* melted at 264–267°. The yield was 24 g. or 76 % of theory.

# CCCXIX. A FRUCTOSE ANHYDRIDE FROM THE LEAVES OF THE BARLEY PLANT.

BY HELEN KEMP ARCHBOLD AND ALICE MABEL BARTER.

*From the Department of Plant Physiology and Pathology, Imperial College of Science and Technology, London.*

(Received October 11th, 1935.)

In determining the sugar content of a cold water extract of dried barley leaves, it was found that the estimate of total sugar was considerably higher if hydrolysis was effected by heating with  $N/5$  sulphuric acid in a boiling water-bath for 10 min., than if treatment with 0.1 % invertase was employed. The sample of invertase was obtained from the British Drug Houses and under the conditions employed inversion of sucrose was complete. In one experiment the value for total sugar obtained after acid hydrolysis was 2.72 % of the fresh weight of the leaves, whilst after enzymic hydrolysis it was only 1.33 %. Separate estimates of fructose and glucose showed that the excess of reducing sugar resulting from the acid treatment was almost entirely fructose. These observations led to an attempt to isolate a fructose anhydride from the leaves.

It has long been known that fructose anhydrides occur in cereals [Müntz, 1878] and in bulbs [Wallach, 1886]. More recently their presence in the Gramineae has been reported by de Cugnac [1931], and by Kizel and Kretovitsch [1934], and their constitution has been discussed by Challinor *et al.* [1934] and by Schlubach and Koenig [1934]. The presence of these compounds in the barley grain was recorded by Tanret [1891], and in the stems and leaf sheaths of the barley plant by Colin [1925] and Belval [1924; 1933]. As far as can be ascertained their presence in the leaf lamina has not hitherto been demonstrated, in fact both Colin [1925] and de Cugnac [1931] state that these compounds do not invade the leaf parenchyma, although they have been found in the leaves of the iris [Augem, 1928], and of the yucca [Schlubach and Florsheim, 1931].<sup>1</sup>

The barley leaves from which a fructose anhydride has now been isolated were detached from plants which had received a full manurial treatment. The seeds were sown on 3. iv. 33, and the collection of leaves was made 10-11 weeks later, when the ears were emerging from their sheaths. Subsequent work has shown that it is unlikely that fructose anhydrides accumulate in the leaves before this stage of the plant's development.

*Preparation of material for water extraction.* Green leaves (7 kg.) were detached from the plants at the stage described above and plunged into boiling 95 % alcohol in such quantity that the final alcohol concentration was 75-80 %. After extracting under a reflux condenser for 5-6 hours, the alcoholic extract was poured off and the residual leaf material dried at 80-90°. It was then ground to a powder and again extracted with 95 % alcohol for 4 hours and dried at 95°. The product, a straw-coloured powder, was now free from sugars, waxes and green pigments and constituted 60 % of the total dry weight of the leaves.

<sup>1</sup> Since this work was completed a paper has appeared by Yemm [1935] in which the presence of a fructose anhydride in some barley leaves is inferred from the results of sugar determinations.

The bulk of the fructose anhydride remains undissolved by this treatment, but a small amount was later recovered from the alcoholic extract.

*Preparation and precipitation of the water extract.* 100 g. lots of the dried powder were shaken in 3 litres of cold water for 10 hours, and the extract was then filtered off at the pump. An amount equivalent to 12 % of the total dry weight of the leaves was extracted by this treatment. The aqueous extract was evaporated *in vacuo*, below 40°, to an eighth of the original volume and an equal volume of 95 % alcohol then added in order to remove the bulk of the inorganic material. The precipitate so obtained had an ash content of 60–70 %; the remaining 30–40 % of organic material was not further examined.

The filtrate from this precipitate was evaporated to a twelfth of its volume and then poured slowly and with stirring into a large excess of 95 % alcohol, the final concentration of alcohol being about 80 %; the crude fructose anhydride was precipitated as a gum by this treatment. After removal of the supernatant liquid the gum was taken up in a little water and the solution poured cautiously into a large excess of absolute alcohol. A creamy white precipitate separated, which was washed with absolute alcohol by decantation and then dried *in vacuo* over sulphuric acid for several days and finally at 100° for 1 hour. The yield of crude material was 6.7 % of the total dry weight, or half the total amount of material extracted by water. Determination of the reducing power of the original aqueous extract, after hydrolysis with  $N/5$  sulphuric acid, showed a total sugar content equivalent to 8.4 % of the dry weight. Therefore, allowing for the ash content of the precipitate (16 %), about 66 % of the fructose anhydride in the water extract was precipitated by 80 % alcohol. The yield of crude product can be somewhat improved by further recovery as barium salt from the combined alcoholic filtrates.

*Treatment of the crude fructose anhydride.* In the first instance purification of the product was attempted by repeated reprecipitation from alcohol and by dialysis. It was found, however, that fractional precipitation with baryta was a much more satisfactory procedure. Consequently 93 g. of the crude product were dissolved in 50 % alcohol and saturated baryta was added in amounts of about 70 ml. at a time. After each addition alcohol was added to maintain the concentration at 50 %. The first five fractions were contaminated with a substance giving a bright yellow barium salt and varied in colour from yellow to cream. These were set aside. After the addition of 370 ml. of baryta the next addition gave a white precipitate. Three white fractions were obtained using 250 ml. baryta for each fraction.

After removal of barium in the usual way the aqueous solutions of these fractions (nos. 6, 7 and 8) were evaporated to small bulk and the purified product was precipitated by pouring the solution into absolute alcohol. The precipitates were quite white, and after drying a pure white powder was obtained in each case.

*Hydrolysis of fractions 6, 7 and 8.* Hydrolysis was effected by heating in a boiling water-bath with  $N/5$  sulphuric acid, and the total reducing power and fructose content of the hydrolysate were determined by a modification of the Harding and Downs copper reduction micro-method, and by the Kolthoff method as described by Van der Plank [1935].

The reducing power of the hydrolysate reached a maximum after 5 min. heating and remained constant for half an hour, after which it began to fall owing to destruction of fructose. A standard time of 15 min. was used in testing the various samples. The results are shown in Table I, together with the values obtained from a sample purified by dialysis and alcohol precipitation, followed by separation as the barium salt.

Table I. *Ash content, specific rotation, and sugar content after hydrolysis of samples of fructose anhydride.*

Method of preparation	Yield (g.) (from 93 g. see p. 2690)	Ash %	Specific rotation	% sugar after hydrolysis. Calculated as fructose	Fructose as % total reducing power after hydrolysis
Alcohol* precipitation and dialysis	—	3-5.5	$[\alpha]_D^{18} - 25^\circ$ to $-29^\circ$	88-95	90
Alcohol precipitation, dialysis and baryta fractionation	—	0.16	$[\alpha]_D^{15} - 35^\circ$	105.5	94
Baryta fractionation:					
Fraction 6	11.9	3.1	—	98	—
Fraction 7	10.4	4.1	—	98	95
Fraction 8	3.8	1.9	—	100	89

\* This sample gave on combustion C 42.7; H 6.0%.  $C_{12}H_{22}O_{11}$  requires C 42.1; H 6.4%.  $(C_6H_{10}O_5)_n$  requires C 44.4; H 6.2%.

*Reprecipitation of fractions 6 and 7.* Fractions 6 and 7 were again precipitated by three separate additions of baryta. The first two fractions (20 ml. baryta) were of a faint cream colour and rather small in amount. The fructose anhydride was regenerated in the usual way from the third fractions, which were pure white, and from the second fraction of no. 6, the other fractions being discarded. The ash content was considerably reduced by this procedure and a higher value obtained for the total sugar content after hydrolysis (Table II).

Table II.

Fraction	Yield (g.)	Ash (%)	% sugar in the hydrolysed product. Calculated as fructose	Fructose as % of total reducing power after hydrolysis
6 <sub>2</sub>	1.4	4.0	102	95
6 <sub>3</sub>	3.6	0.15	103	95
7 <sub>3</sub>	2.6	0.40	104	92
A	3.8 (from 5.8 g.)	None	105	95
B	1.3 (from 5.8 g.)	None	104	94

Since there appeared to be no material difference between the two pure white samples 6<sub>3</sub> and 7<sub>3</sub> they were combined and refractionated using two 10 ml. lots of baryta. The two samples, A and B, obtained by this final fractionation gave on hydrolysis the results shown in Table II. All the remaining ash had been removed, but the percentage of sugar obtained on hydrolysis was not sensibly altered.

The final product was a pure white amorphous powder, very soluble in cold water, insoluble in absolute alcohol, non-reducing towards copper and precipitated slowly by basic lead acetate. The lead precipitate was redissolved by a slight excess of the reagent.

The maximum yield of reducing sugar on hydrolysis was 105% of the weight of fructose anhydride taken. This would correspond to complete hydrolysis of a disaccharide or to 94% hydrolysis of the molecule  $(C_6H_{10}O_5)_n$ . In no case was the fructose found equivalent to more than 95% of the total reducing power after hydrolysis. There appears therefore to be a small amount of glucose (or other reducing substance) produced on hydrolysis in addition to the fructose. There may also be a little non-reducing material but this remains uncertain until the size of the molecule is known.

*The specific rotation of samples of fructose anhydride.* Although the samples A and B discussed above showed no difference in chemical properties they did not show the same specific rotation. The values obtained were  $[\alpha]_D^{18}$  A  $-37.8^\circ$ , and B  $-28.1^\circ$ . The value for sample A agrees fairly well with that for the sample prepared by alcohol precipitation, dialysis and baryta treatment ( $-35^\circ$ ; see Table I), and also with the value for fraction 6<sub>2</sub> which was  $-37^\circ$ . A low value,  $-26^\circ$ , similar to that found for B, was obtained from a sample prepared from the filtrates remaining after the precipitation of the crude product with 80 % alcohol.

*The action of invertase on samples of fructose anhydride.* All the samples were slowly attacked by invertase, but the rates of hydrolysis of the different preparations varied considerably. Thus after an incubation period of 4 hours at  $38^\circ$ , with an enzyme concentration of 0.02 %, the degree of hydrolysis of samples A and B was 11.7 and 17.2 % respectively. Under the same conditions only 4 % of fraction 6<sub>2</sub> was hydrolysed, whilst values of the order of 20 % were found for fractions isolated from the alcoholic extract of the green leaves and from the filtrates after precipitation of the aqueous extract by 80 % alcohol (see p. 2690). All these samples gave the same results on acid hydrolysis as those already quoted for samples A and B.

The results of the measurement of specific rotation and of susceptibility to invertase action suggest that a mixture of two or more fructose anhydrides was present in these barley leaves; further, the more soluble fractions have a lower negative rotation and are more readily attacked by invertase than the less soluble.

A sample of the fructose anhydride is now in the hands of Prof. Haworth, who is studying the constitution of these compounds obtained from different sources. Further investigation is therefore suspended until these results are available.

#### SUMMARY.

A fructose anhydride has been isolated from a water extract of leaves obtained from barley plants at the time of emergence of the ear.

The product, a pure white amorphous powder, readily soluble in cold water, was obtained by precipitation of the aqueous solution with alcohol, followed by fractional precipitations with baryta until there was no change in the amount of sugar produced on hydrolysis of the regenerated product.

Hydrolysis of the final product yielded a solution containing reducing sugar equivalent to 105 % of the weight of anhydride taken, of which 94 % was fructose.

Samples were obtained which differed both in specific rotation and in susceptibility to invertase action, although otherwise exhibiting the same properties as those quoted above. The more soluble fractions had a specific rotation of about  $[\alpha]_D^{18} -27^\circ$  and were more readily attacked by invertase than the less soluble, which had a specific rotation of about  $-37^\circ$ .

It is concluded that a mixture of two or more anhydrides was present in the leaves.

## CCCXX. PHYTIN IN HUMAN NUTRITION.

BY ROBERT ALEXANDER McCANCE  
AND ELSIE MAY WIDDOWSON.

*From The Biochemical Department, King's College Hospital, London.*

*(Received October 22nd, 1935.)*

It has long been recognised that a large proportion of the total phosphorus of cereals and other vegetable foodstuffs may be present in the form of phytin, the calcium magnesium salt of inositolhexaphosphoric acid. This compound, which is insoluble, is manufactured commercially, and has been widely recommended and accepted as a tonic [Ihm, 1929; Paulsen, 1929] and as a readily assimilable form of phosphorus for human nutrition [Starkenstein, 1910; Hutchison and Mottram, 1933]. On the other hand Plimmer [1913] showed that phytin was not hydrolysed by the intestinal enzymes and evidence has been accumulating in recent years that its phosphorus is not available. This is contrary to the results of earlier workers [see Plimmer, 1913] who found that the administration of phytin by mouth led to an increased excretion of inorganic phosphorus in the urine. Bruce and Callow [1934] however using a high Ca-low P diet for rats claimed that the rachitogenic effect of cereals was due to the fact that phytin-P was unavailable. Lecoc and Barban [1935] have shown that in rats aromatic phosphates do not have an antirachitic action, whereas carbohydrate phosphates have. Phytin-P was found to be quite unavailable. On the other hand Harris and Bunker [1935] found no correlation between the degree of rickets produced by a corn diet in rats and the absolute or relative amounts of phytin-P which the diet contained. The further question whether the absorption of calcium from the gut may not be interfered with by phytic acid was considered by Bruce and Callow [1934], but Forbes and Irving [1931] found that phytin-Ca was as available to rats as that of  $\text{CaCl}_2$ .

Many workers have determined the phytin-P of cereals, mainly by modifications of Heubner and Stadler's [1914] original method. This depended upon the extraction of phytic acid from the finely-ground cereal by means of HCl, and the titration of the extract with an acid solution of ferric chloride in the presence of ammonium thiocyanate. The phytin was precipitated as its insoluble iron salt, and the end-point determined by the appearance of the red colour. Later workers have experienced considerable difficulty in determining the end-point of the titration, and modifications have been introduced by Rather [1917], Averill and King [1926] and Harris and Mosher [1934]. Recent results have however fully confirmed the earlier view that phytin-P may form a large percentage of the total P in cereals [Andrews and Bailey, 1932; Knowles and Watkin, 1932; Harris and Mosher, 1934]. Nuts have also been investigated [Averill and King, 1926] but no systematic study appears to have been made of the phytin in other plant foods, and an attempt has been made in the present investigation to determine phytin in fruits, vegetables, nuts, cereals and cereal products commonly eaten in this country.

*Method of determination.*

Heubner and Stadler's [1914] method was first tried but was found to be unsatisfactory, partly owing to the difficulty of determining the end-point of the titration, even when modifications suggested by later workers were introduced, and partly because such large amounts of dried fruit or vegetable were sometimes required in order to obtain a reasonable titration.

Young [1935] has devised a method for the determination of phytin, which, like the earlier ones, is based on the precipitation of phytic acid by  $\text{FeCl}_3$  from HCl solution: instead of using a titration method, the phytic acid solution is heated with a known amount of  $\text{FeCl}_3$  and after removal of the precipitate the excess iron is determined colorimetrically as thiocyanate.

Similar precipitation with excess of  $\text{FeCl}_3$  has been used in the present investigation, but the phytin has been directly determined by estimation of the amount of phosphorus present in the ferric phytate precipitate.

*Reagents.* HCl,  $N/2$  and  $N/6$ .

Ferric chloride (A.R.) solution in  $N$  HCl containing 0.5 mg. ferric iron per ml. NaOH 2% (approx.).

*Procedure.* 5–10 g. of dried, finely-ground material were shaken in a small glass-stoppered bottle with 100 ml.  $N/2$  HCl for 2 hours to extract the phytic acid: 10 to 40 ml. of the filtered extract were neutralised to phenolphthalein with NaOH, rendered slightly acid with HCl and made up to 50 ml.

Duplicate 20 ml. aliquots were treated in 50 ml. centrifuge-tubes, with 4 ml. of the  $\text{FeCl}_3$  solution. The tubes were heated in a boiling water-bath for 15 min. to flocculate the precipitate of ferric phytate, cooled, centrifuged and the supernatant liquid poured off. The precipitate was washed with 5 ml.  $N/6$  HCl, centrifuged again and the acid decanted.

The precipitate was then stirred up with 2 ml. distilled water and heated in a boiling water-bath for a few minutes. 2 ml. of 2% NaOH were then added, and the heating continued for a further 15 min. The solution containing the phytin as sodium phytate was filtered into a Kjeldahl flask, the precipitated ferric hydroxide was well washed with hot water and the washings were added to the filtrate in the flask.

1 ml. of conc.  $\text{H}_2\text{SO}_4$  and 1 ml. of 65%  $\text{HClO}_4$  (A.R.) were added, and the mixture incinerated very gently until completely digested. It was then heated strongly for 60 min. to drive off any residual  $\text{HClO}_4$ . When cool, about 20 ml. of water were added and the contents of the flask just neutralised to phenolphthalein with 40% NaOH. The solution was then made up to 100 ml. An aliquot of 5 or 10 ml. was taken in a test-tube and the volume made up to 10 ml. in every case. A blank solution containing 1 ml. conc.  $\text{H}_2\text{SO}_4$  almost neutralised with 40% NaOH and made up to 100 ml. was used for the dilution. Standards containing 0.025, 0.05, 0.10 and 0.20 mg. of P were prepared by diluting 0.25, 0.50, 1.0 and 2.0 ml. of a standard solution (containing 0.1 mg. of P per ml.) to 10 ml. with the blank solution. The subsequent procedure was exactly as described by Briggs [1922].

Various steps in the method have been tested as follows:

(a) Preliminary experiments were carried out on a 0.1% solution of commercial phytin in  $N/2$  HCl in order to determine whether slight variations in the  $p_H$  of the solution affected the amount of ferric phytate precipitated, and to ensure that the presence of inorganic P did not increase the apparent phytin-P of the solution.

10-ml. samples of the standard phytin solution were treated exactly as described above, but the  $p_H$  at which the ferric phytate was precipitated varied from very faintly acid to the acidity of the solution usually employed ( $N/6$ ). Aliquots of the phytin solution were similarly treated

in the presence of an approximately equal amount of inorganic P. All the results agreed to within 2%, indicating that phytin was quantitatively precipitated at all the degrees of acidity tested whilst the inorganic P remained in solution.

(b) The phytin-P in the phytin solution, determined as described above, was 19.0 mg. per 100 ml. The phytin-P calculated as the difference between the total and the inorganic P was 20.3 mg. per 100 ml. showing a recovery of 94%. Since commercial phytin is not pure and may well contain traces of other phosphorus-containing substances, this result was regarded as satisfactory.

(c) In order to determine whether all the phytin was extracted in 2 hours and to study the effect of varying the amounts of extracted material in relation to the volume of acid used, four samples of oatmeal, two of 5 g. and two of 10 g., were shaken with 100 ml. *N/2* HCl for 2 hours. One of the 5 g. samples and one of the 10 g. samples were filtered immediately, whilst the other two were left soaking in the acid overnight and then shaken for a further 2 hours before being filtered. The phytin-P of each extract was determined in duplicate as already described. The results are shown in Table I. They indicate that the extraction of phytin was complete after 2 hours, and that the whole of the phytin was extracted by 100 ml. of acid whether 5 g. or 10 g. of dried material were used.

Table I. *Effect of different methods of extraction on the phytin-P content of oatmeal.*

				Phytin-P mg. per 100 g.
10 g. oatmeal extracted	2 hours with 100 ml. <i>N/2</i> HCl			223
10 g.       "	20       "	"	"	229
5 g.       "	2       "	"	"	220
5 g.       "	20       "	"	"	224

*Determination of total P.* 0.2 g. of dried ground material was incinerated with  $\text{H}_2\text{SO}_4\text{-HClO}_4$ , the mixture neutralised, washed out and analysed for P as already described.

#### *The phytin content of foods.*

Each food to be analysed was purchased from 3 or more different shops in order to obtain an average sample. The mixed material was dried at 100° and ground as finely as possible. The analytical results in Table II, in agreement with previous analyses, show that phytin is a characteristic and abundant constituent of whole cereals and grains and of foodstuffs prepared therefrom, in some cases 40–50% of the total P being present in this form. Removal of the husk and germ considerably reduces the total and relative amounts of phytin-P. Thus, wholemeal flour contained nearly half its total P as phytin-P, whilst white flour contained very much less. It should be noted however that in spite of its high content of phytin-P wholemeal flour still contained almost twice as much non-phytin- or "available" P as white flour.

All legumes investigated contained phytin-P, which in dried pulses ranged between 38 and 50% of the total. Fresh legumes, on the other hand, whether raw or cooked, contained considerably less of their total P in this form (5–20%). The reason for this difference is not apparent, but it must be remembered that dried butter beans, blue peas *etc.* are still alive, and that metabolic changes may have taken place within them during storage. Tinned peas are cooked while fresh, and it is to be expected that these will contain about the same amount of phytin-P as fresh peas.

Phytin was present in carrots and parsnips, whilst turnips, swedes and onions contained none. Potatoes and Jerusalem artichokes contained about 20% of their total P as phytin-P.

Table II. *Phytin content of foods.*

Edible portions only have been analysed. The results have been expressed on a fresh weight basis.

Food	Total P mg.	Phytin- P mg.	Phytin- P as %	Food	Total P mg.	Phytin- P mg.	Phytin- P as %
	per 100 g.	per 100 g.	total P		per 100 g.	per 100 g.	total P

				Apples	8.5	0	0
				Bananas	28.1	0	0
				Blackberries	25.9	4.2	16.2
				Figs, dried*	91.5	11.9	13.0
				Prunes*	83.0	0	0

\* The results of these "dried" foods have been expressed on a purchased weight basis.

As reported by Averill and King [1926] phytin was found to be present in nuts, and in peanuts, cobnuts, almonds and coconuts about half the total P was present in this form. Cocoa and chocolate also contained phytin, 24 % of the total P in cocoa occurring as this compound.

Green-leaf and stem vegetables contained no phytin and none was found in mushrooms. It was entirely absent from the pulp of fruit, whether fresh or dried, but fruits with a large number of "edible" seeds, *e.g.* figs and blackberries, contained small amounts.

#### *The fate of ingested phytin.*

Experiments have been carried out on 4 subjects, the authors (M.) and (W.), a healthy woman (L.) and a boy (S.) aged 4½, who had been operated on for an inguinal hernia 6 days previously. The basal diet was not weighed but was

chosen to be as far as possible phytin-free, and on this diet it was ascertained that the faeces contained only very small amounts of phytin. W. and S. ate weighed amounts of Hovis bread as their sole source of phytin, and samples were set aside daily for analysis. M. ate Hovis bread and blackberries, and L. took 2 g. of phytin (Messrs Ciba, Ltd.) daily in divided doses. The three adults consumed almost exactly the same amount of phytin on each day of their experiment, but the boy's intake was rather more variable. After a fore period of 2-3 days, faeces were collected in 2-, 3- or 4-day periods, well mixed, and duplicate aliquots of 50 to 100 g. taken. The latter were dried at 100°, ground up in a mortar and analysed for total P and phytin-P as already described.

The results are given in Table III.

Table III. *The excretion of ingested phytin.*

	Average daily intake phytin-P mg.	Average daily output in faeces		% of phytin-P ingested which was recovered in faeces
		Phytin-P mg.	Total P mg.	
M. Period 1 (2 days)	416	181	950	43.4
M. " 2 (2 " )	436	206	975	47.5
M. " 3 (3 " )	436	192	860	44.0
W. " 1 (2 " )	330	150	765	45.5
W. " 2 (3 " )	336	120	635	35.8
W. " 3 (2 " )	336	134	830	39.8
L. " 1 (3 " )	370	194	765	52.5
L. " 2 (4 " )	370	231	790	62.5
S. " 1 (3 " )	101	25	505	25.0
S. " 2 (3 " )	114	24	840	21.4

These experiments show that the three adults excreted 36-63 % of the ingested phytin unchanged in the faeces. Of these, L. who took commercial phytin excreted the most. The child (S.) excreted a much smaller percentage, but this experiment, which was carried out in a children's ward, was not so accurate as those on the adults. A variable fraction of the phytin therefore proved to be absolutely unavailable in every case, but the fact that the remainder did not appear again in the form in which it was eaten is no proof that the phosphorus in it was available even to this extent, for the phytin may have been broken down by the intestinal flora at a level below that at which absorption could take place. The total P in the faeces was far in excess of the amount of phytin-P ingested so this may have been the case.

The present experiments therefore provide concrete evidence that as much as half the phytin-P eaten may be unavailable, but they should not be considered to provide any definite evidence as to the fate of the remainder.

#### *Dietetic importance of phytin.*

A study has recently been completed on the individual, freely-chosen diets of 63 men and 63 women of the English middle class. By means of the figures in Table II the phytin-P intakes of these men and women have been calculated and compared with the total P in their diets.

Table IV. *Total P and phytin-P intake of men and women.*

(Results expressed as g. per day.)

	Men Mean of 63	Women Mean of 63
Total P	1.61	1.13
Phytin-P	0.04	0.04
Non-phytin-P	1.57	1.09
Non-phytin-P as percentage of total P	98	97

No individual took more than 20 % of his total P in the form of phytin. Relative amounts as high as this were the exception, and only occurred if large quantities of brown bread were being eaten. In most cases less than 10 % of the total food P was phytin-P. In this country therefore, where we live on a varied diet and derive most of our phosphorus from animal and not from vegetable sources, 80–100 % of the total phosphorus eaten is in available form (average 97.5 %). In other countries, however, where cereals, either whole or milled, constitute by far the largest portion of the diet, the total P may be a wholly incorrect guide to the available P intake.

#### SUMMARY.

1. A method for estimating small amounts of phytin is described. The phytin was extracted by HCl, precipitated as the ferric salt and the P in the precipitate estimated after sulphuric-perchloric acid incineration.
2. The phytin in 64 foodstuffs has been determined.
3. The fate of ingested phytin in the human body has been investigated in 3 adults and a child, and it has been shown that 20–60 % is excreted unchanged in the faeces.
4. Phytin-P constitutes less than 5 % of the total P of the average middle-class diet in this country.

One of us (E. M. W.) is indebted to The Medical Research Council for a part-time grant.

# CCCXXI. THE POTENTIOMETRIC DETERMINATION OF POLYPEPTIDES AND AMINO-ACIDS.

By ERNEST WILLIAM BALSON, GEORGE ALAN EARWICKER  
AND ALEXANDER LAWSON.

*From University College, Southampton.*

*(Received October 25th, 1935.)*

DURING the course of work on proteolytic hydrolysis the need arose for accurate determinations of small quantities of amino-acids and polypeptides in mixtures. It appeared from the literature that two possible methods were available, firstly, the conductimetric titration of Widmark and Larssen [1923], and secondly, the colorimetric titrations employing aqueous alcohol [Willstätter and Waldschmidt-Leitz, 1921], or acetone [Linderstrom-Lang, 1928], and the formaldehyde method [Sørensen, 1907].

Willstätter and Waldschmidt-Leitz recommend a first titration with alkali in 40 % alcoholic solution followed by another in 97 % alcohol for the separate determination of peptides and amino-acids in mixtures. It was decided to follow the course of such titrations potentiometrically.

For such a method to be reliable, there should be in the 40 % alcohol titration curve a point of inflection corresponding to the total peptide. For the accurate determination of this point by a colorimetric method, two conditions must be realised. Firstly, the  $p_H$  change about this point should be of a high order, and secondly, the point should occur at a fixed  $p_H$ . It has however been shown in this communication that for mixtures of leucylglycylglycine and glycine in 90 % alcohol, the peptide titrates at  $p_H$  9.25 when 17 % glycine is present, and at  $p_H$  7.5 when 92 % glycine is present. Except in limiting cases, the slope about the peptide inflection in the titration curve is small, and further with such limiting cases, the shapes of the curves show that the constituent present in smaller amount will almost certainly be missed when a colorimetric method is used. These considerations will apply equally well to 40 % alcohol. The accuracy of the second titration (in 97 % alcohol) is not however open to question unless the indicator employed changes at a different  $p_H$  from that corresponding to the neutralisation of the weakest acid present.

The degree of separation of the constituents of amino-acid-peptide mixtures attainable by potentiometric titration will be governed by the following factors. Any such mixture when titrated with alkali will show inflections in its titration curve corresponding to the various acids present. In theory the titration curve should contain inflections for every acid present unless the differences between the logarithms of their dissociation constants are less than 1.2 [Auerbach and Smolczyk, 1924].

In practice however, the dissociation constants fall into several main groups each containing acids of very nearly equal dissociation constants. Such groups will appear in the titration curve as a single acid, *i.e.* will give rise to one inflection. Thus glycine, alanine and leucine, having approximately equal dissociation constants ( $p_{K_a}$  9.8 in water), will titrate together as a single acid. Similar considerations apply to simple peptides such as alanylglycine, glycylglycine, and

leucylglycine ( $pK_a$  7.8), so that a mixture containing all the above substances will give two inflections, one corresponding to the total peptide, and the other to the total  $-\text{COOH}$  of the mixture. Glutamic acid ( $pK_a$  6.0 and 10.3) will give a first inflection before the peptide, and therefore, if also present, will be readily detected. On the other hand, histidine and asparagine, having  $pK_a$  8.8 and 9.0 respectively, will titrate between the peptide and the amino-acids. One could not expect however, on theoretical grounds to obtain inflections for each acid in a mixture of, for example, leucylglycylglycine, glycine and histidine, and this is shown to be the case, the glycine and peptide inflections alone being apparent. The curves of arginine and lysine, as would be expected from their high  $K_a$  values, show no inflections whatever and hence cannot be determined by this method.

In practice such points of inflection, the final one excepted, do not appear clearly in the titration curve owing to the buffering of the untitrated acid. In order to determine their exact positions it was found necessary to adopt a differential method of plotting. Curves obtained by this method show peaks corresponding to each inflection. For this method to be successfully applied the titrant must be added in small increments and this necessitates a somewhat high degree of accuracy in the E.M.F. measurement, readings being required to 0.2 mv.

#### EXPERIMENTAL.

*The titration vessel* (Fig. 1) consisted of two parts connected by a ground-glass joint. The lower portion held about 12 ml. liquid and the substances to be titrated were weighed directly into it on a micro-balance. The outlet from the cell was connected to a U-tube containing 90 % alcohol.

The titrations were carried out in 90 % aqueous alcohol at 25°, using a hydrogen electrode, and to obtain satisfactory results it was found necessary to wash the hydrogen with a 90 % alcohol-water mixture before passing it into the titration vessel, and to pass it through the NaOH solution before each titration to remove traces of dissolved oxygen. This second precaution enabled the electrodes to reach equilibrium in 1–2 min. as compared with 5–10 min. with untreated sodium hydroxide. It was found advantageous to employ small electrodes consisting of 1–1.5 cm. of platinum wire as these came to equilibrium more quickly than the larger plate type. Various methods of plating were tried but the electrodes in all cases became rapidly poisoned, becoming useless after about three titrations and sometimes failing after two. Thus to ensure satisfactory results each electrode was used once only. Platinised, gold-plated electrodes were employed as they came to equilibrium rapidly and were easily stripped of black. The electrodes were prepared by gold plating from a solution of gold hydroxide in potassium cyanide (prepared according to the instructions of Clark), using a current of 2 mA. for 5 min., this being followed by platinising from a 3 % solution of chloroplatinic acid containing a trace of lead acetate till the electrode was just covered with black. Electrodes of this type gave E.M.F.'s in water which were usually identical and never more than 0.2 mv. apart, but in alcohol they were

usually 1–2 mv. apart and remained so during the whole of a titration. The contact between the bridge solution (saturated aqueous potassium chloride) and the titration vessel was made in a cotton-wool plug in the side arm of the half cell, which consisted of a silver-silver chloride electrode in saturated potassium chloride solution. The cotton-wool plug was renewed after each titration. The sodium hydroxide was added in increments of 0.02–0.05 ml. depending on the total titre. From the values of E.M.F. and ml. sodium hydroxide added the differential curves were constructed as follows: If the E.M.F. recorded was  $E_1, E_2, E_3, E_4$ , etc. corresponding to  $N_1, N_2, N_3, N_4$  ml. of sodium hydroxide added, then the slope of the curve at the point  $N_2$  was taken to be  $(E_3 - E_1)/(N_3 - N_1)$ , and that at the point  $N_3$  as  $(E_4 - E_2)/(N_4 - N_2)$ . The potentiometer was a Pyc standard slide wire instrument graduated to 0.2 mv. incorporated in a ballistic type of valve potentiometer of similar design to that of Morton [1931], but employing a Marconi receiving valve, type HL2. A Tinsley portable galvanometer of the damped type was employed, the apparatus being sensitive to 0.1 mv.

### RESULTS.

The alcoholic sodium hydroxide was standardised against A.R. glycine in the apparatus.

All amounts are expressed as g. mol.  $\times 10^6$ .

#### Titration of histidine hydrochloride.

(Fig. 2A) NaOH, 0.0523 *N*; 25.8 histidine hydrochloride present.

Found: 1st peak (HCl) ... ..	25.1
2nd peak (HCl + histidine) ... ..	51.0

#### Mixtures of glycine and leucylglycylglycine.

Exp.	Conc. of NaOH	Glycine actual	Leucylglycylglycine		Total COOH		
			Actual	Found	Actual	Found	
(Fig. 2 B).	1	0.0420 <i>N</i>	19.8	97.1	99.6	116.9	116.6

#### Mixture of glutamic acid and leucylglycylglycine.

(Fig. 2E) NaOH, 0.0523 *N*, actual amounts were: leucylglycylglycine, 20.2; glutamic acid, 27.65.

	Actual	Found
Found: 1st peak (glutamic acid)	27.65	26.15
2nd peak (glutamic acid + peptide)	47.85	47.10
3rd peak (total —COOH)	75.50	75.90

#### Mixture of histidine hydrochloride, glycine and leucylglycylglycine.

(Fig. 2F) NaOH, 0.0523 *N*, actual amounts were: leucylglycylglycine, 25.3; glycine, 58.0; histidine hydrochloride, 38.7.

	Actual	Found
Found: 1st peak (HCl)	38.7	38.7
2nd peak (HCl + peptide)	64.0	62.8
3rd peak (total —COOH)	160.7	162.0

Histidine gave no observable inflection at the theoretical point,  $H$ , on the curve.

### SUMMARY.

1. The titration of mixtures of amino-acids and polypeptides representative of types to be expected in protein hydrolysates is carried out in 90 % aqueous alcohol.

2. The degree of separation which can be attained in such mixtures is discussed.

3. The  $p_H$  of the end-point for such peptides as leucylglycylglycine in mixtures with an amino-acid such as glycine has been shown to vary over a range of nearly two  $p_H$  units depending on the proportions of the constituents. Thus any colorimetric titration becomes unreliable and must be replaced by potentiometric titration, for which a special method of differential plotting is described, this method being specially serviceable in the determination of mixtures.

# CCCXXII. THE APPLICATION TO URINE OF TOLLENS'S NAPHTHORESORCINOL TEST FOR CONJUGATED GLUCURONIDES.

By HAROLD BERNARD SALT.

*From the Clinical Laboratory, Droitwich Spa.*

*(Received October 23rd, 1935.)*

It is well known that the administration of certain drugs, notably those containing an actual or potential hydroxyl group, results in an increase in the quantity of glucuronic acid excreted in the urine. The increase is due to the formation of a conjugated compound of the drug and glucuronic acid and represents a process of detoxication which is attributed to the liver. Quick [1927] pointed out that we had no direct evidence that the liver is the organ responsible for this detoxication but proof has now been furnished by Hemingway *et al.* [1934]. When the liver is seriously disordered, its failure to eliminate such drugs as conjugation compounds has been made the basis of a test for the detoxicatory efficiency of the liver [Beaumont and Dodds, 1931]. The liver test involves the application of Tollens's naphthoresorcinol reaction to urine and many variations of this have been described in the literature. Tollens's reaction consists essentially in heating glucuronic acid or a conjugated glucuronide with naphthoresorcinol and hydrochloric acid, a blue substance being formed giving a blue-violet solution in ether.

*Discussion of Tollens's reaction applied to urine.* The test, when applied directly to urine, has been found by many to be unsatisfactory owing to the presence of interfering substances. The writer has invariably found a deep red colour, masking any blue or violet, when testing many urine samples. In order to remove the interfering substances, different methods of preliminary treatment of the urine have been proposed.

The use of mercuric acetate described by Roger [1916] does not remove glucose, the presence of which may inhibit the test [Brule *et al.*, 1925; Roger, 1916]. Hence, this method is not applicable to glycosuric urine. Furthermore, when used by the writer, even with urine collected after ingestion of aspirin and free from sugar, a most unsatisfactory red colour was always obtained, making any interpretation impossible.

The urine test described by Beaumont and Dodds [1931] has been found to be quite unsatisfactory. According to Tollens [1914], the addition of basic lead acetate to urine results in complete precipitation of conjugated glucuronides, a fact confirmed by present experiments. It is therefore useless to test the filtrate for the presence of such. Like the mercuric acetate filtrate, the basic lead acetate precipitate yielded an unsatisfactory red colour when Tollens's test was applied to it. Precipitation of urine with zinc acetate and testing both filtrate and precipitate also failed to give a satisfactory test.

Attention was then turned to methods of ether extraction as recommended by Neuberg and Schewket [1912]. However, using urine collected after ingestion of aspirin, the conjugated compound was found to be insoluble in ether. This was confirmed by extracting "aspirin urine" with ether in a Clausen extractor as described by Quick [1924]. The ether extract gave a negative Tollens's test (colourless).

It may be mentioned here that throughout this work aspirin has been used exclusively as a glucuronogenic drug. The conjugated compound found in the urine is perhaps an unusual one, as Quick [1932] has obtained evidence that salicylic acid undergoes double conjugation with glucuronic acid, there being formed one glucoside linkage and one ester linkage.

A new method of treatment was then sought. The principle was suggested by the method of separating glucuronic acid monobenzoate described by Quick [1926]. The interfering substances are first removed from urine by precipitating with lead acetate in slightly acid solution and centrifuging. The glucuronic acid compound is then completely separated from the supernatant fluid by neutralising and precipitating with basic lead acetate. Tollens's reaction is applied to the basic lead acetate precipitate.

By this method glucose is separated, as it is not precipitated by basic lead acetate. Pentoses cannot interfere, as even if precipitated with the glucuronic acid compound, the colour which they give with naphthoresorcinol is insoluble in ether [Tollens, 1914]. The final extraction with ether yields a blue-violet colour, the depth of which is roughly proportional to the amount of glucuronic acid present. The replacement of ether by chloroform or benzene suggested by Neuberg and Saneyoshi [1912] was found to be unsatisfactory.

The actual technique now recommended for the urine test was developed from the following results, applying Tollens's reaction to the different fractions of urine collected for 12 hours after aspirin ingestion.

Table I.

Test fraction		Result of test
Urine untreated	—	Deep red
Urine <i>plus</i> excess lead acetate	Precipitate	Pale violet
	Supernatant	Deep red
Urine <i>plus</i> excess basic lead acetate	Precipitate	Deep red
	Supernatant	Pale red
Urine <i>plus</i> just sufficient lead acetate	Precipitate	Colourless
	Supernatant (*)	Deep red
Supernatant from above (*) <i>plus</i> excess basic lead acetate	Precipitate	Deep violet
	Supernatant	Red-brown

It is seen that both untreated urine and the basic lead acetate precipitate from urine fail to give a satisfactory test. An excess of lead acetate precipitates a little glucuronide, but just sufficient lead acetate avoids this and removes certain interfering substances. The supernatant fluid from this first lead treatment still contains interfering substances, but treatment with basic lead acetate yields a precipitate containing all the glucuronide and giving a satisfactory colour test, whilst the interfering substances remain in the supernatant.

A similar series of results was obtained when 5% glucose was added to the urine, except that the last supernatant yielded a deeper red-brown colour.

#### THE TECHNIQUE OF THE URINE TEST.

##### *Solutions required:*

33% acetic acid.

5% lead acetate.

Approximately *N* sodium hydroxide.

10% basic lead acetate prepared by heating 20 g. tribasic lead acetate with 200 ml. water to boiling. After boiling and stirring for a few minutes, the

solution is allowed to cool and then filtered. A large amount of insoluble matter is discarded.

Hydrochloric acid, 50 % by volume.

1 % pure naphthoresorcinol in absolute alcohol.

*Procedure.* The urine is mixed and rendered slightly acid with acetic acid. A 5 ml. portion is pipetted into each of four 10 ml. capacity centrifuge-tubes. To the tubes respectively, 0.25, 0.5, 0.75 and 1.0 ml. lead acetate are added, the contents mixed and centrifuged. To each, one drop lead acetate is added and the tube selected in which precipitation is seen to be just complete. If no tube is completely precipitated, a further 1.0 ml. lead acetate is added to each and the procedure repeated. Complete precipitation is thus effected but an appreciable excess of lead acetate is avoided. In some cases it may be necessary to add a further 1.0 ml. lead acetate to each and to repeat the procedure again.

The supernatant fluid is poured from the selected tube into another centrifuge-tube and sodium hydroxide added dropwise until the first permanent precipitate of lead hydroxide is observed. Then 3.0 ml. basic lead acetate are added, the contents mixed and centrifuged. To ensure complete precipitation, one drop more of the reagent is added and if necessary a further quantity of basic lead acetate is added and the process is repeated until an excess is present and precipitation is complete. The supernatant fluid is poured away and the deposit washed on the centrifuge by thoroughly stirring with 5 ml. water and separating.

The precipitate is transferred to a large test-tube using two 5 ml. portions of dilute hydrochloric acid (1:1) from a pipette. 0.5 ml. naphthoresorcinol solution is added and mixed. The tube is heated in boiling water for 5 min., then cooled in running water, 10 ml. ether are added, well shaken and allowed to separate. The ether layer is removed to a clean test-tube and examined by transmitted white light. The colour of the ether solution is noted at once, as the colour fades on standing.

#### *Results of the test applied to urine.*

The test described was applied to a number of urine specimens and the results are summarised in Table II.

Table II.

	No. of specimens	Result
Normal urine	10	Faint pink to pale violet
Urine after aspirin ingestion	7	Pale violet to deep violet
Blank with reagents	—	Colourless

It was found that the drug is almost wholly eliminated by normal persons in 12 hours after administration.

Attempts were then made to apply the test quantitatively. For this purpose calcium glucuronate was prepared by the method of Kiliani [1921] and 0.1098 g. dissolved in 100 ml. water, so that 1 ml. contained 1 mg. glucuronic acid. Aliquot portions of this solution were heated with naphthoresorcinol and hydrochloric acid to determine the limit of sensitivity of the test and the colour proportionality.

When read in the colorimeter, exact proportionality was not found, though the colour intensity was roughly proportional to the amount of glucuronic acid present.

Table III.

Glucuronic acid mg.	Colour produced
2.0	Very deep blue
1.0	Deep blue
0.5	Pale blue
0.1	Colourless

Aliquot portions of the calcium glucuronate solution were then added to 5 ml. portions of normal urine and the complete test including double lead precipitation carried out.

Table IV.

Glucuronic acid added to 5 ml. urine mg.	Colour produced
1.0	Deep violet
0.75	Violet
0.5	Very pale violet
0.25	Brownish
Nil	Faint pink

It is seen that the test is sensitive to 0.5 mg. glucuronic acid present in 5 ml. urine. The colours did not match well with those obtained from a solution of pure calcium glucuronate. This, together with the lack of true colour proportionality and the unavoidable errors involved in ether extraction, rendered attempts at a quantitative method unprofitable. However, an estimate of the amount of glucuronic acid present in a sample of urine may be made by testing different decreasing amounts of urine until the quantity which just gives a positive test is determined; this quantity of urine will contain about 0.5 mg. glucuronic acid.

It is suggested that this test applied to 24-hourly urine specimens would yield an index of the excretion of naturally formed phenolic toxic substances. Obviously all drugs capable of conjugating with glucuronic acid must be eliminated at the time of the test. The reaction would then indicate the extent of excretion of conjugated compounds of phenol, cresol, indole and skatole and might therefore suggest the extent of absorption of intestinal putrefaction products of this nature, provided that the liver were not seriously disordered. A number of 24-hourly normal specimens have been tested and found to give negative or only faintly positive results, using 5 ml. test portions.

*The test for the detoxicatory efficiency of the liver.*

The principle of the test is the detection of an increase in the amount of conjugated glucuronide excreted after the administration of some toxic drug. Many drugs have been used by various workers, *e.g.* aspirin, sodium salicylate, naphthol, chloral hydrate or camphor by the mouth, or camphor in olive oil injected. Of these aspirin was chosen, as its use is attended with least ill effects. It was found to be quite satisfactory in producing an increase in glucuronide excretion in normal subjects. A dose of 15 grains by the mouth was used.

Urine is collected during the day for 12 hours before the aspirin is given and preserved with a little toluene. The drug is then administered and a further 12 hours' urine collected during the night. The volumes are noted and the naphthoresorcinol test is carried out simultaneously on the two specimens. If the liver has responded to the drug, a much more intense violet colour will be given by the second urine specimen than by the first.

It has been stated by Brule *et al.* [1925] that the presence of urotropin in the urine inhibits the reaction. Thus all other drugs should be excluded during the test.

Much evidence has previously been put forward that a seriously disordered liver fails to carry out its detoxicating function by conjugating toxic substances with glucuronic acid. However, it appears that the naphthoresorcinol test has hitherto been not altogether reliable. It is suggested therefore that the liver test should be re-investigated in cases of liver disease, especially since recent experiments have definitely shown that the liver is responsible for such detoxicatory reactions.

Liver test results obtained from several normal subjects by the method described have shown a prompt and definite increase in the urinary glucuronic acid, following aspirin ingestion.

#### SUMMARY.

Methods are discussed for the application to urine of Tollens's naphthoresorcinol test for conjugated glucuronides. An improved technique for the urine test is described. It is suggested that the test might be used to indicate increased absorption of intestinal putrefaction products. Using aspirin as a glucuronogenic drug, a method of testing the detoxicatory efficiency of the liver is given.

# CCCXXIII. THE DETERMINATION OF GLUTAMINE IN THE PRESENCE OF ASPARAGINE.<sup>1</sup>

BY HUBERT BRADFORD VICKERY, GEORGE WALTER PUCHER  
AND HAROLD EUGENE CLARK<sup>2</sup>

(*Connecticut Agricultural Experiment Station, New Haven, Connecticut*),

AND ALBERT CHARLES CHIBNALL AND ROLAND GORDON WESTALL  
(*Biochemical Department, Imperial College of Science and Technology,  
South Kensington*).

(Received October 26th, 1935.)

ALTHOUGH glutamine has been known for many years to be a constituent of certain plant tissues [Schulze and Bosshard, 1883], no method whereby this substance can be separately distinguished from asparagine and determined with accuracy has appeared until recently. Glutamine has indeed frequently been isolated but its properties are such that isolation has only qualitative significance. Chibnall and Westall [1932] noted that the amide group of glutamine is extensively hydrolysed by heating at 100° for 3 hours at  $p_H$  8, whereas asparagine is scarcely affected by this treatment. Accordingly they suggested that the glutamine content of a plant tissue extract might be estimated with an error of about 10 % if the increase in ammonia, on hydrolysis of the extract at  $p_H$  8, were multiplied by a factor (1.4) derived from the results of experiments on the pure substance. They further observed diminution of the amino-N, during such hydrolysis of glutamine, at a rate parallel with the production of ammonia: this fall in the amino-N of a plant tissue extract, under the conditions of hydrolysis mentioned, provides valuable additional evidence of the presence of glutamine and distinguishes the latter from other substances, especially urea and allantoin, which likewise give rise to ammonia on mild hydrolysis.

Recent experience with Chibnall and Westall's method in the Connecticut Agricultural Experiment Station laboratory indicated that the accuracy could be appreciably improved by certain modifications in the technique, and in particular, in the reaction chosen for the hydrolysis. Chibnall and Westall found that glutamine is apparently very little hydrolysed at  $p_H$  6 and 7; the observations at New Haven, on the contrary, showed it to be completely hydrolysed at these reactions. A joint study in the two laboratories of the factors involved revealed the presence of a systematic error in the method used by Chibnall and Westall to determine the ammonia produced by hydrolysis at these particular reactions. They had employed phosphate buffers at  $p_H$  6 and 7 and had subsequently determined ammonia by distillation *in vacuo* with excess of magnesium oxide. Under these conditions insoluble magnesium ammonium phosphate may form, which is not completely decomposed during distillation at 40°. We have since found that Kostychev [1931] has drawn attention to the possibility of this source of error in the determination of ammonia.

The extreme scarcity of glutamine at the time of Chibnall and Westall's experiments prevented the thorough investigation of the stability of glutamine

<sup>1</sup> A part of the expense of this investigation was borne by the Carnegie Institution of Washington.

<sup>2</sup> National Research Council Fellow.

at various reactions which would have revealed this difficulty. Recently however an improved method of isolation [Vickery *et al.*, 1935] has permitted re-investigation of the stability of glutamine in both the New Haven and the South Kensington laboratories with a view to improving the method of its determination in plant tissues. The results are embodied in the present paper.

*The stability of glutamine.*

The fundamental operation upon which all determinations of amides depend is the estimation of ammonia. Some of the difficulties that beset this determination have been discussed by Pucher *et al.* [1935]. Their procedure (modified from Boussingault [1850]) was employed for the following determinations.

*Effect of  $p_H$ .* A specimen of glutamine containing 18.94% N was employed. Of this 0.1056 g. was dissolved in water and diluted to 200 ml.; 5 ml. therefore contained 0.25 mg. of amide-N. The solution was unchanged in amide-N after 5 days at 0°. Aliquots of 5 ml. were mixed with 10 ml. of an appropriate buffer solution in 25 × 200 mm. test-tubes which were closed by rubber stoppers carrying a short length of fine-bore capillary tubing. At reactions of  $p_H$  7 or higher a small bulb trap charged with 3 ml. of 0.1 *N* HCl was attached to the capillary to provide against loss of ammonia. The test-tubes were placed in a boiling water-bath for 2 or 3 hours and were then kept in cold water until analysed (not over 3 hours). The buffer solutions used were mixtures of 0.05 *M* succinic acid and 0.05 *M* borax for the range  $p_H$  3 to 5, and 0.1 *M* potassium dihydrogen phosphate and 0.05 *M* borax for the range  $p_H$  6 to 9 [Kolthoff, 1926]. The individual mixtures were checked by the quinhydrone electrode at room temperature (22 to 24°), and were all within 0.05 unit of the required  $p_H$ . After being heated with glutamine as described, the reactions did not change more than  $\pm 0.1$   $p_H$  unit.

The data in Table I show that glutamine is least unstable in the region of its isoelectric point, but, outside this range, is rapidly and completely hydrolysed. The data for  $p_H$  3, 4 and 5 confirm the earlier figures of Chibnall and Westall.

Table I. *Hydrolysis of glutamine at different reactions in buffered solutions at 100°.*

Figures are % of the amide-N liberated as ammonia.

$p_H$	...	3.0	4.0	5.0	5.3	5.5	5.7	6.0	7.0	8.0	9.0
2 hours' hydrolysis		89.8	77.0	69.2	73.1	76.3	79.0	98.6*			
3 hours' hydrolysis		91.0	85.3	81.6	81.1	81.2	89.4	98.3†	99.0	98.4	99.6

\* The average of 11 determinations ranging from 94 to 103.

† The average of 6 determinations ranging from 96 to 101.

*Effect of temperature.* 5 ml. samples of standard glutamine solution were heated in a water-bath at different temperatures with 10 ml. of buffer for 2 hours; the tubes were cooled and Nessler's solution was added to the contents, which

Table II. *Hydrolysis of glutamine at  $p_H$  6.5 in 2 hours at various temperatures.*

Figures are % of the amide-N liberated as ammonia.

Temperature °C.	Hydrolysis %
44 $\pm$ 2	3.2 to 3.8
63 $\pm$ 2	17.0 to 19.0
80 $\pm$ 2	53.0 to 56.0
100	98 to 100

were then diluted to 50 ml. and read at the spectrophotometer. Suitable controls with standard ammonia solution showed that this procedure was permissible. The results in Table II show that it is necessary to heat glutamine to 100° in order to bring about complete hydrolysis in 2 hours.

*Effect of time.* The data given in the fifth column of Table III show the time course of the hydrolysis of glutamine at  $p_H$  6.5. Within the accuracy of the method as applied to the measurement of 0.25 mg. of  $NH_3$ -N, hydrolysis is evidently complete in 2 hours.

*The products of hydrolysis of glutamine.*

Table III shows the rate at which amino-N disappears when a solution of glutamine is heated to 100° at  $p_H$  6.5. 5 ml. samples of standard glutamine solution containing 0.5 mg. of amide-N were heated with 10 ml. of buffer for the stated times. The ammonia was then distilled off in the usual way, the residue was acidified with 2 ml. of glacial acetic acid and diluted to 50 ml., and of this solution 5 ml. were used to determine amino-N in the Van Slyke manometric apparatus [Peters and Van Slyke, 1932]. The values for 15 and 30 min. are each the average of 6 closely agreeing determinations, that for 60 min. the average of 4, and the rest are the averages of duplicates.

Table III. *The rate of hydrolysis of glutamine at  $p_H$  6.5 and 100°, as measured by the change in the  $\alpha$ -amino-N as well as by the production of ammonia; 1.0 mg. of glutamine-N present in each case.*

Time of heating min.	Apparent amino-N mg.	Disappearance of $\alpha$ -amino-N %	Ammonia-N mg.	Increase of ammonia-N as % of total amide-N %	Ratio decrease in amino-N/increase in ammonia-N

120	0.014	98.4	0.492	98.4	1.80

The rate of ammonia production was ascertained in a separate series of experiments in which the hydrolysates were treated directly with Nessler's solution.

Glutamine in freshly prepared solution yields 90% of its total N as nitrogen gas in the Van Slyke manometric apparatus in 4 min. at 22.5°. This observation confirms that of Chibnall and Westall who found 92% after 10 min. shaking in the ordinary Van Slyke amino-N apparatus and, assuming that all of the  $\alpha$ -amino-group reacts in this time, indicates that approximately 80% of the amide group also is decomposed. The figures in column 3 of Table III are calculated on the assumption that the amide-N that was not hydrolysed reacted to the extent of 80% with nitrous acid. A correction of this magnitude was therefore applied to the apparent amino-N figures in order to ascertain the proportion of the  $\alpha$ -amino-N that had disappeared from the system; the figures agree reasonably well with the proportion of the amide-N that was hydrolysed (column 5). It is obvious that the hydrolysis of glutamine is accompanied by a parallel loss of  $\alpha$ -amino-N.

A number of observations indicate, however, that the behaviour of glutamine in neutral aqueous solution is by no means simple. For example, a solution which has been stored at 0° for several days may yield only 84% or less of its

N in the Van Slyke apparatus although in this period no appreciable quantity of ammonia is liberated. Furthermore, partly hydrolysed solutions of glutamine invariably contain less  $\alpha$ -amino-N than they should when this is calculated according to our best information regarding the behaviour of glutamine amide-N in the Van Slyke apparatus. Perhaps when the true structure of glutamine has been elucidated by modern physico-chemical methods the anomalous behaviour of this substance in solution may become clear.

The ultimate product of the amide hydrolysis of glutamine is evidently a substance which does not contain amino-N. The most obvious explanation is that hydrolysis is accompanied by lactam formation to give pyrrolidone-carboxylic acid.

In order to make certain that this is the case, 1.0 g. of glutamine (0.190 g. N) was boiled with 100 ml. of water for 4 hours: the solution then contained 0.0845 g. of ammonia-N and 0.0117 g. of apparent amino-N, indicating hydrolysis of 88.9 % of the amide groups and disappearance of 96.4 % of the  $\alpha$ -amino-groups. The solution was concentrated *in vacuo* to 10 ml. and a drop of silver nitrate solution was added; this precipitated a trace of brown flocculent material which was filtered off and discarded. The filtrate was then evaporated in a vacuum desiccator to 8 ml. and 1.2 g. (1 equivalent) of silver nitrate dissolved in 2 ml. of water were added. Crystallisation of the silver salt began at once, and the white needles were filtered off and washed with alcohol after the solution had been chilled for a few hours. The yield was 1.281 g. or 82.3 % of the theoretical, calculated from the amino-N data, or 89.1 % calculated from the data for amide hydrolysis. The crystals contained 45.4 % Ag and 5.92 % N (calc. 45.7 % and 5.94 % respectively). Clearly therefore the chief products of the hydrolysis of glutamine in substantially neutral solution are pyrrolidonecarboxylic acid and ammonia.

#### *The stability of asparagine.*

Inasmuch as asparagine is frequently present in plant extracts together with glutamine, the stability of the former amide was also studied. The conditions adopted were identical with those employed with glutamine, save that the standard solution of asparagine contained 1 mg. of amide-N in the 5 ml. aliquot added to the buffer solution. The data in Table IV show that asparagine, like glutamine, is most stable in the region of its isoelectric point, but that the proportion hydrolysed at  $p_H$  7 and above in 3 hours is quite appreciable. It is obviously inadvisable to conduct glutamine determinations in the presence of asparagine if the reaction of hydrolysis is above  $p_H$  7: the result of the hydrolysis at  $p_H$  6.5 for 2 hours shows that interference from asparagine with a glutamine determination at this reaction is ordinarily negligible.

Table IV. *Hydrolysis of asparagine at different reactions in buffered solutions at 100°.*

Figures are % of the amide-N liberated as ammonia.

$p_H$	...	4	5	6	6.5	7	8	8.5	9
3 hours' hydrolysis		2.4	1.8	2.1	2.6*	6.6	14.0	16.3	18.5

\* Hydrolysis for 2 hours.

In order to hydrolyse the amide group of asparagine completely it is necessary to employ dilute acid. Vickery and Pucher [1931] recommended 2 N  $H_2SO_4$ , and a hydrolysis time of 6 hours. Subsequent experience has shown these conditions to be unnecessarily severe. When asparagine is heated with N  $H_2SO_4$

86.7 % of the amide-N is hydrolysed in 1 hour, 94.9 % in 2 hours and 100.2 % in 3 hours. Evidently therefore a 3-hour period of hydrolysis at 100° with  $N H_2SO_4$  is adequate.

*The determination of glutamine in solution.*

The method of determining glutamine that has been developed from the foregoing data depends on the observation that its amide group is completely hydrolysed in 2 hours at 100° within the range  $p_H$  6 to 7, whereas the amide group of asparagine is very slightly affected under these conditions. Owing to differences of equipment, the practical details of the method differ slightly in the two laboratories. In the New Haven laboratory the procedure is as follows.

A suitable aliquot of the solution (not over 5 ml.) is pipetted into a 25 × 200 mm. test-tube together with 10 ml. of buffer solution at  $p_H$  6.5. The tube is closed with a rubber stopper carrying 20 cm. of 1 mm. bore heavy wall glass tubing, the lower surface of the stopper and the orifice of the tube being previously moistened with a few drops of water. The tube is placed in a constant-level boiling water-bath for exactly 2 hours and is then removed and cooled in cold water, a few drops of water being at the same time allowed to be drawn down through the capillary in order to wash back any ammonia that may have volatilised. The contents of the tube are washed into the ammonia distillation apparatus [Pucher *et al.*, 1935] with 20 ml. of water, and the ammonia is distilled *in vacuo* at 40° after addition of 3 ml. of a reagent prepared by dissolving 5 % of borax in 0.5  $N$  NaOH. The distillate is diluted, treated with 5 ml. of Nessler's [Koch and McMeekin, 1924] solution, made up to a volume of 50 ml. and the extinction coefficient determined by means of a Zeiss-Pulfrich spectrophotometer. The quantity of ammonia in the distillate is obtained from the calibration curve of the instrument and is corrected for the apparatus blank.

For the determination of glutamine in plant tissue extracts a suitable aliquot, together with water to make 5 ml., is placed in the test-tube together with 10 ml. of a phosphate-borate buffer of such reaction and molar strength as to give a final reaction, after the 2-hour hydrolysis, close to  $p_H$  6.5. In many cases a 0.1  $M$  buffer of  $p_H$  7.0 is satisfactory, but occasionally buffers of two or four times this concentration may be required. Trials are necessary in each new case. The hydrolysis and determination of the ammonia are conducted as described, and the final figure is corrected for the free ammonia of the tissue.

The procedure employed in the South Kensington laboratory is similar, but the ammonia in the distillate is normally determined by titration with standard acid in the usual way.

*The determination of asparagine in solution.*

The method is based on the data for the stability of asparagine already given. An aliquot of the solution together with sufficient water to make a total volume of 5 ml. is mixed with 1 ml. of 6  $N$   $H_2SO_4$ , and heated in a test-tube as described for 3 hours at 100°. The solution is then washed into the ammonia distillation flask with 20 ml. of water; 5 ml. of 1  $N$  NaOH are added followed by 5 ml. of the alkaline borate mixture and the ammonia is distilled, determined and corrected for the blank in the usual way.

This procedure, when applied to a plant tissue extract, gives the total amide-N together with the free ammonia-N of the solution. Corrections for the glutamine amide-N and the free ammonia-N are accordingly subtracted, and the difference is regarded as asparagine amide-N. It is evident that any error

arising from the presence of interfering substances such as urea and allantoin is calculated as asparagine; further discussion of this point is reserved, however, for a subsequent paper.

*The determination of glutamine and asparagine in mixtures.*

In order to calculate the glutamine and asparagine amide-N content of a mixture of these two substances, it is necessary only to determine the total amide-N after hydrolysis with *N* acid and the glutamine amide-N after hydrolysis at  $p_{\text{H}}$  6.5. Data from a series of such determinations shown in Table V indicate that satisfactory results are obtained.

*The preparation of plant tissue for amide determinations.*

For the determination of the glutamine content of plant tissues it is essential to prepare a representative sample in a form suitable for analysis without danger of partial hydrolysis of the glutamine. Four methods hold out some promise of success: first, extraction with cold water after cytolysis of the fresh tissue with ether according to the method of Chibnall [1923]; a convenient technique has been described by Pucher *et al.* [1935], but it has been found that in order to extract amides completely the residue from the hydraulic press must be thoroughly ground in a plate-type grinding mill before being washed as they describe for the extraction of ammonia; furthermore it is probably desirable in most cases to heat the extract rapidly to 80° to coagulate any protein, and to cool, make to volume and filter before aliquots are taken for analysis. A second method is that of grinding with sand in a mortar, the resultant pulp being diluted with water, rapidly heated to 80° to coagulate protein, cooled, filtered and the residue extensively washed. This method is particularly advantageous for small samples of succulent tissue and is customarily employed in the South Kensington laboratory. A third method consists of freezing the tissue, properly protected against loss of water, best with carbon dioxide snow; subsequently the material is rapidly thawed, the juice is expressed and the tissue is washed substantially as in the first method mentioned. This procedure is likewise applicable in general only to small quantities of tissue. Lastly, there is the method of drying at some suitable controlled temperature in an oven equipped with means to circulate air over the tissue, a method that can be applied to any quantity of material up to the capacity of the drying oven.

The choice among these methods depends on a number of factors. Among the more important is the question of size of sample necessary to ensure that it shall be adequately representative. A few g. only of a small-leaved species may be sufficient; with large-leaved species such as tobacco, much larger samples are essential. Equipment is likewise very important; laboratories that do not possess a hydraulic press are necessarily restricted in their choice. In addition there is the question of preservation of material until the analytical operations can be undertaken.

Information available at present indicates that only the first two methods, which imply prompt analysis of the fresh tissue extract, are entirely safe. The method of drying possesses so many advantages however and is in fact necessary in so many practical cases, that we have devoted much study to it.

The equipment with which the following tests were carried out consists of a commercial cabinet drier with 12 trays  $16 \times 30$  in. arranged in two banks. Air is circulated at the rate of approximately 217 ft. per min. over the trays by a motor-driven fan, and heat is supplied from a gas burner protected by baffles in the lower part of the cabinet. The gas supply to the burner is controlled by a thermostat which may be adjusted to any temperature between 50 and 120° and which controls within  $\pm 2^\circ$ .

Tomato plants were dissected into stem and leaf portions, which were separately cut up with shears into small pieces. Samples were withdrawn from each portion for extraction by the ether-cytolysis method and for drying. Determinations of ammonia-N, total amide-N, glutamine amide-N and amino-N were carried out immediately upon the fresh tissue extracts, and similar analyses were performed on aqueous extracts of the dry tissue. These extracts were prepared by heating 3-5 g. at 80° with 80 ml. of water for 10 min. with constant stirring; the beaker was then rapidly chilled, the contents transferred to a 100 ml. flask, made to volume and centrifuged, and aliquots of the clear fluid, filtered if necessary through a plug of glass wool, were taken for analysis. That this method of extraction is adequate was shown by parallel determinations of free ammonia in samples of dry tissue and in the extracts. In 10 experiments the average ratio between extract ammonia-N and dry tissue ammonia-N was 1.01, and the maximum variation in only two cases exceeded 5%. Such close agreement of the free ammonia-N values indicates that hydrolysis of glutamine during the preparation of the dry tissue extracts was negligible.

Table VI shows the results of analyses of the leaf and stem tissues from three separate batches of plants, dried at the specified temperatures, compared with data obtained on extracts prepared from the fresh tissue. One batch was used for each experiment, collections being made at weekly intervals. The plants were grown in crocks in a greenhouse and had been heavily fertilised with ammonium sulphate in order to stimulate the synthesis of glutamine [Vickery *et al.*, 1934].

It is clear that the agreement between the values found in the leaf tissue is satisfactory; even when dried at 90° the value in the dry tissue is less than 4% lower than in the extracted tissue. The data for the stem tissue are somewhat less satisfactory, the glutamine values in the dried tissue being somewhat higher than in the extracts. This was not due to failure to extract completely, since glutamine determinations on the extracted residues showed that less than 2% of the glutamine originally present remained unextracted. In general it may be concluded that the differences between the glutamine values in extracts and in dried tissue are within the analytical variations to be expected of the method, and it is clear that, if the drying be carried out in the vicinity of 80° under proper conditions, satisfactory determinations of glutamine may be secured.

Table VI. *Comparison of the composition of tomato leaves and stems as determined from analyses of fresh tissue extracts and of tissue dried at various temperatures.*

Ratio: glutamine amide-N of dried / glutamine amide-N of extracted sample	0.982		0.972		0.984		1.06		1.07		0.906	

An experiment was conducted in which a drying temperature of 60° was used. The data were not satisfactory for several reasons, the chief being that a sample of tissue exceptionally low in glutamine was employed. Although the dried sample showed little increase in free ammonia or decrease in glutamine over the extracted sample, there was a very marked increase in soluble N and in amino-N, indicating that during the slow drying at 60° (2.25 hours) considerable autolysis of protein occurred: a drying temperature in excess of 60° is therefore to be desired. It may be inferred that the time during which the tissue is exposed to the temperature of the drying oven is of great importance: the conditions should be so adjusted that this shall be as short as possible.

#### *The determination of glutamine in plant tissues.*

Apart from the problem of preparing tissue for analysis in such a manner as to avoid significant hydrolysis of glutamine, a serious difficulty arises from the possible presence of other substances that may evolve ammonia during the analytical operations essential to determination of the amide. Chibnall and Westall have discussed the stability of urea and allantoin in this connection: both give rise to appreciable amounts of ammonia under the conditions of the glutamine hydrolysis, and our more recent studies of these substances show that interference, particularly from urea, may become serious if more than traces are present. Fortunately, however, it is relatively easy to demonstrate the absence of these substances. Inasmuch as the decomposition both of urea and of allantoin is incomplete in 2 hours at  $p_{\text{H}}$  6.5 and 100°, it suffices to conduct hydrolyses under these conditions for 2- and 4-hour periods; if there is no increase in ammonia in the longer period, the absence of urea and allantoin may be inferred.

The data in Table VII are presented chiefly to illustrate the reproducibility of glutamine determinations carried out according to the directions in a preceding section. The tissues had been dried at 80° as already described, and the analyses were conducted on extracts of the dried tissue in order to eliminate interference from proteins. The data for the tomato plant illustrate the extraordinary

enrichment in glutamine which occurs when this species is grown in culture solutions that provide ammonia as the sole source of N; attention has been directed to this elsewhere [Vickery *et al.*, 1934].

*The behaviour of the apparent amino-N during the  
hydrolysis of glutamine.*

Chibnall and Westall pointed out that the decrease in the apparent amino-N of the solution when the amide group of glutamine is hydrolysed in nearly neutral solution may serve as qualitative evidence of the presence of this substance in a plant extract. This behaviour cannot be employed for quantitative calculation because of the possibility that unstable peptides may be present which may undergo hydrolysis with the production of actual amino-N. Furthermore, glutamic and hydroxyglutamic acids likewise lose amino-N, owing to ring formation, on being heated in neutral solution and, if present, would introduce an additional source of error. Nevertheless the criterion is frequently one of real value in forming a judgment as to the qualitative composition of plant extracts.

The ratio of the decrease in apparent amino-N to the increase in ammonia-N which occurs when a solution of pure glutamine is hydrolysed at  $p_{\text{H}}$  6.5 varies from 2.1 to 1.8 as the hydrolysis progresses (see last column, Table III); the final value is that to be expected from a plant extract that contains glutamine, provided that no other substances are present which produce ammonia or which change in amino-N content under the same conditions.

Data illustrating the magnitude of the ratio as observed in tissues high in glutamine are shown in Table VI. Further data are given in Table VIII. It is clear that the results are unequivocal only when quite appreciable amounts of glutamine are present.

Table VIII. *The changes in amino-N of various plant extracts on hydrolysis at  $p_H$  6.5 for 2 hours at 100°.*

The present method of determining glutamine must be applied with discrimination and only after careful consideration of the possible sources of error. In the case of tissues known from other data to store relatively large proportions of this substance there is little doubt of the trustworthiness of the results, for the error introduced by the partial decomposition of such traces of urea, allantoin or other unstable substances as may be present is probably negligible. The method is therefore extremely valuable as a means of investigating the metabolism of the amides in known glutamine-storing plants. But the general application of the method to the determination of an additional factor in the customary examination of the N fractions of plant tissues, especially when the quantity involved is relatively small, must be deprecated in the present very incomplete state of our qualitative knowledge of the composition of plants.

#### SUMMARY.

The procedure advocated by Chibnall and Westall for the determination of glutamine in plant tissues has been revised in the light of more recent information on the stability of this substance. The amide group has been found to be completely hydrolysed when glutamine is heated at 100° for 2 hours at  $p_H$  6.5; accordingly the quantity of glutamine amide-N in an extract of plant tissue can be determined by estimation of the increase in ammonia-N that occurs on hydrolysis under these conditions; interference from asparagine is negligible.

Attention is drawn to the possibility of interference from urea and allantoin, and a method is suggested whereby such interference may be detected.

The decrease in amino-N of an extract, on hydrolysis under the conditions mentioned, is shown to be a valuable qualitative criterion of the presence of glutamine, as has previously been indicated by Chibnall and Westall.

The chief application of the method as at present developed is to the study of plant material known from other considerations to elaborate glutamine.

Data on the stability of glutamine with respect to hydrogen ion activity and to temperature are included, together with a demonstration that the chief products of the hydrolysis of glutamine at essentially neutral reaction are ammonia and pyrrolidonecarboxylic acid.

# CCCXXIV. THE CHEMICAL COMPOSITION OF TEETH.

## II. THE COMPOSITION OF HUMAN ENAMEL AND DENTINE.

BY JOANE HYLTON BOWES AND MARGARET MARY MURRAY.

*From the Department of Physiology, Bedford College, University of London.*

*(Received October 28th, 1935.)*

It is known that the chief inorganic constituent of enamel and dentine is calcium phosphate. Bassett [1917] concluded that the calcium phosphate was in the form of hydroxyapatite. Gassmann [1910; 1921; 1928] found in bones and teeth a constant ratio of  $10\text{Ca} : 6\text{P} : 1\text{CO}_2$  indicating that the bone compound was  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCO}_3$ , calcium carbonatophosphate or carbonatoapatite. The best evidence that teeth are composed of apatite was obtained from X-ray analysis by de Jong [1926], Taylor and Sheard [1929], Roseberry *et al.* [1931], Thewlis [1932], Klement and Tromel [1932] and Bredig [1933]. From this method it is difficult to decide which form of apatite is present and no information is gained about substances present in small amounts. The most complete chemical analysis of the inorganic constituents was made by Gabriel [1894] on ox teeth and his figures are those most generally quoted. Since that time determinations have been made of the amounts of certain elements and their possible variations under different conditions. Gassmann [1921] determined Ca, P,  $\text{CO}_2$  and Mg of whole teeth, working chiefly with wisdom teeth. Kaushansky [1930; 1932] and Howe [1926] studied the Ca, P and Mg in caries and pyorrhoëa. These and other determinations were made on crowns or whole teeth, that is on a variable mixture of enamel and dentine. Fish [1932] investigated the Ca content of dentine of different ages and under different conditions.

With regard to the organic matter of enamel, Evans [1913] concluded that there was 1-2 % present. Sprawson and Bury [1928] stated that, judged from the combustible carbon and the nitrogen, only a very small amount of protein is present.

The present investigation aimed at obtaining values for the composition of sound human teeth as a basis for comparison. The material was very carefully selected: therein lies the difference between this and much previous work, carried out before it was realised that even sound teeth vary in structure. Sound (non-carious) permanent premolar teeth of children under 14 years of age, removed for orthodonture purposes, were collected from the school clinics. These teeth were examined with a lens and probe in the manner described by Mellanby [1923; 1934] and separated into five classes, comprising perfect teeth and four degrees of hypoplasia. For a tooth to be graded as perfect it had to have a hard, smooth, shining surface devoid of markings, pits or fissures. Such teeth were rarely encountered. This can be understood, since a perfect tooth is not likely to occur in an overcrowded mouth. The next class of tooth, showing a very mild degree of hypoplasia, usually restricted in area, occurred more frequently. The determinations reported in this investigation were all carried out on this class of tooth. In this way we avoided variations in composition due to differences in age and type of tooth [Fish, 1932].

*Preparation of material.*

After classification the teeth were placed in hot water, brushed and filed to clean the surface and then put into neutral 95% alcohol till required. Enamel and dentine were analysed separately and were obtained in the following manner. The cleaned tooth was held in a hand clamp and the enamel ground from the outside of the tooth by a rapidly rotating cylindrical file of very hard steel. The file was surrounded by a celluloid guard and the fine enamel powder was directed down a chute into a beaker below by means of a gentle current of air. By careful examination of the tooth every few minutes, it was possible to ensure that only enamel was removed in this way, grinding being stopped before the dentine was reached. To obtain the dentine, the cutting edge of the tooth was then ground down on a carborundum wheel till the dentine was exposed. The file was replaced by a dentist's rose head burr and the dentine bored out and collected as in the case of enamel until only a shell of dentine and enamel remained. The separated powders were freed of iron by means of a magnet and magnetised needle. The material was further examined with a lens for specks of extraneous matter such as cotton fibres *etc.* The enamel and dentine powders were dried at 105–110° and transferred to a vacuum desiccator until used for analysis.

*The analyses.*

These included determinations of total ash and nitrogen to give an indication of the organic matter and combined water and carbon dioxide. The nitrogen was estimated by micro-Kjeldahl incineration and distillation followed by nesslerisation. The inorganic analyses included the determination of Ca, Mg, Na, K, P, CO<sub>2</sub>, Si, F and Cl. The Ca, P and Mg were determined on the same dilute acid solution of the material, the Ca by titration with *N*/50 KMnO<sub>4</sub> of the calcium oxalate precipitated at *p*<sub>H</sub> 5.6–5.8 and the P by Robison's modification of the Briggs method. The Mg determinations gave considerable trouble. The precipitation as magnesium ammonium phosphate gave very discordant results. The method of Greenberg and Mackay [1932] for the estimation of Mg in blood was modified and successfully applied. For the Na determinations it was necessary to remove the Ca and the phosphate before the zinc-uranyl acetate method of Salit [1932] could be applied. Careful addition of ammonia conveniently removed both as Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>. In the case of dentine, fat and protein extractions were first carried out. In spite of the fact that we used the purest chemicals available, we found it necessary to perform blanks on the reagents and to account for the sodium arising from the glass in the course of manipulations. For the potassium estimations the material was treated with H<sub>2</sub>SO<sub>4</sub> to convert into K<sub>2</sub>SO<sub>4</sub>, taken up in water and filtered. The determination was made by the method of Shohl and Bennett [1928], which involves precipitation as K<sub>2</sub>PtCl<sub>6</sub>, treatment with KI and titration of the resulting iodo-compound with thio-sulphate. The combined CO<sub>2</sub> was estimated in a specially adapted Van Slyke apparatus which had at the top a one-way tap with a large bore (7 mm.). Through this tap the substance was introduced as a fine powder by a special device. This consisted of a very small glass funnel with a stem of such a size and length that it would go through the tap. The funnel was fitted with a cork which carried a glass plug for the stem. The plug was inserted into the stem of the funnel, about 0.1 g. powder introduced, the cork placed in position and the whole weighed on a watch glass. The sample was introduced into the apparatus by placing the stem through the tap and pulling out the cork and plug; the powder then dropped into the burette. The funnel was re-weighed immediately. 2*N* HCl was used to liberate

the  $\text{CO}_2$ . We found it necessary to standardise the conditions of the determinations on a known mixture of pure  $\text{Ca}_3(\text{PO}_4)_2$  and  $\text{CaCO}_3$ . The  $\text{CO}_2$  determinations were also carried out on samples after they had been heated in a furnace to a temperature and for a time previously determined as sufficient to drive off the  $\text{CO}_2$  from  $\text{CaCO}_3$  and  $\text{MgCO}_3$ . The chlorine was determined by the silver nitrate-thiocyanate procedure in an aqueous extract and on a  $\text{HNO}_3$  solution of the same sample. The determination of the F has been dealt with fully elsewhere [Bowes and Murray, 1935]. Recently we have used distillation of the F as  $\text{H}_2\text{SiF}_6$  by treatment of the material with  $\text{HClO}_4$  and then applied the Zr-alizarin colorimetric determination. Silicon was estimated in whole teeth by the method of King and Stantial [1933]; all processes in this determination were carried out either in platinum or "bakelite" vessels.

In almost all the determinations the methods employed had to be adapted to the particular needs, because the high proportion of  $\text{Ca}_3(\text{PO}_4)_2$  interfered with most of the estimations. The methods were tested on known samples of  $\text{Ca}_3(\text{PO}_4)_2$  to which the particular constituent had been added in suitable proportion. In this way we were able to determine the degree of accuracy to be expected. The determinations on the tooth material were repeated until we could claim an accuracy of 0.2% for the Ca and P, 2% for the Mg and less accuracy for the other elements. We are doubtful as to the presence of K, the values obtained being almost within the limits of experimental error.

#### *Consideration of the enamel results.*

The first thing to be noticed (Table I) is the very small amounts of Si and F. It is continually stated in textbooks that teeth contain significant quantities of both of these elements; moreover F is probably not present in all teeth. The Cl content is greater than the F content. This Cl is part of the tooth substance

Table I. *Composition of enamel.*

	Dry enamel
Ash	95.38 %
Nitrogen	0.156 %
Combined $\text{H}_2\text{O}$ (calculated)	1.347 %
Combined $\text{CO}_2$	1.952 % (After heating 0.54%)
Calcium	37.07 %
Magnesium	0.464 %
Sodium	0.25 % (Aqueous extract 0.1%)
Potassium	0.05 % or less
Phosphorus	17.22 %
Chlorine	0.3 %
Fluorine	0.025 %
Silicon	0.003 % (Whole teeth)
Ca/P	2.153 (Ca/P for apatite is 2.151)
Ca/Mg	79.89
P/ $\text{CO}_2$	8.822

Ca : P :  $\text{CO}_2$  (molar proportions) = 10 : 5.994 : 0.479.

and is not present adventitiously as a salt soluble in water, because before the enamel was dissolved in  $\text{HNO}_3$  for this estimation it was extracted with hot water. The loss in weight on ashing represents the organic matter, the bound water and part of the  $\text{CO}_2$ .

The value of the Ca/P ratio and the relatively small amount of other substances present indicate that a form of apatite  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaX}$  is the chief constituent of enamel, representing approximately 90% of the dry and 95% of the

ashed substance. This is what would have been expected from the results of X-ray analysis. This latter method, however, is not able to distinguish definitely between the various forms of apatite, and opinions differ as to which form represents the bone and tooth compound. The possible forms are chloro-, fluoro-, carbonato-, hydroxy- and oxy-, where the appropriate element or radical represents the X in the general formula stated previously. Bredig [1933] has compared the X-ray patterns of the teeth and bones with the artificially prepared apatites and is of the opinion that the compounds of bone and teeth are essentially the same and are hydroxyapatite. Klement and Tromel [1932] are of the same opinion. Hendricks *et al.* [1932] favour the presence of carbonatoapatite in bone, whilst de Jong states that he is unable to distinguish between the various apatite forms. Dealing with bone, on which much work has been done, opinion also varies as to whether the complex  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaX}$  is the only compound deposited and whether it is necessary to consider the separate deposition of salts such as  $\text{CaHPO}_4$  and  $\text{CaCO}_3$ . Robison [1932] considers that there is no reason to postulate the separate formation of  $\text{CaCO}_3$ . Roseberry *et al.* [1931] state that there is no evidence for the separate deposition. On the other hand, Marek *et al.* [1934], as well as discussing the previous evidence for and against the question of the existence in bone of one single compound, concluded from their own analyses of young pig bone that the  $\text{Ca}_3(\text{PO}_4)_2$  and the  $\text{CaCO}_3$  were deposited separately, because the relative amounts of these two substances were found to vary in different parts of the bone. A similar conclusion was drawn by Burns and Henderson [1934], working on young bone. Gassmann [1921] considered that the ratio  $\text{Ca} : \text{P} : \text{CO}_2$ , found by him in bones and whole teeth, was so near to that required by carbonatoapatite that he deduced that this was the chief constituent of both of these. The values obtained in this investigation did not agree entirely with those of Gassmann who, it must be remembered, worked on whole teeth. Enamel, though probably a form of apatite, is not exclusively carbonatoapatite. It is probably not justifiable to consider the bone and teeth to be of the same chemical composition; dentine but not enamel is comparable with bone. The results reported here show that the enamel and dentine are not identical in their inorganic constituents. In normal enamel the P is probably only present as apatite whereas dentine possibly contains  $\text{CaHPO}_4$  in addition: there are also distinct differences in the  $\text{CO}_2$  contents. Dentine is in all ways more similar to bone; the  $\text{CO}_2$  contents are approximately equal; enamel contains much less  $\text{CO}_2$ . It is significant that enamel, on prolonged heating, does not lose all its carbon dioxide whereas dentine and bone, heated under the same conditions, lose all.  $\text{CaCO}_3$  and  $\text{MgCO}_3$  heated for the same time and to the same temperature also lose all their  $\text{CO}_2$ . It has not been possible to test the effect of heat on carbonatoapatite for no sufficiently pure specimens can be made. Since it is probable that the  $\text{CO}_2$  combined as apatite would be more firmly held, it was assumed that the  $\text{CO}_2$  remaining in the enamel after heating was present as apatite, whilst that driven off was present as  $\text{CaCO}_3$  or  $\text{MgCO}_3$ . Gassmann [1921] emphasised the stability of the complex calcium carbonatophosphate as compared with  $\text{Ca}_3(\text{PO}_4)_2$  and  $\text{CaCO}_3$ . Working on this assumption it is possible, by calculation and deduction on a percentage basis, to form an idea of the probable combination of the elements composing the enamel. The  $\text{CO}_2$  was considered to be distributed in the following way: that remaining in the heated enamel was taken to be present as carbonatoapatite; that driven off by heating to be combined with the Mg and the excess with Ca as carbonate. The amounts of fluoro- and chloro-apatite were calculated from the F and Cl values. The remainder of the Ca was taken to be present as hydroxyapatite. The values obtained by

these calculations are given in Table II. The corresponding figures for P found in this way by calculation agreed within experimental limits with those determined practically. It is possible that a very small amount of organically bound P occurs; this is indicated by the slight rise in Ca/P ratio on ashing.

Table II. *The composition of human enamel found by calculation, using the figures given in Table I.*

	%	Ca % in enamel	P % in enamel
MgCO <sub>3</sub>	1.624	—	—
CaCO <sub>3</sub>	1.331	≡	0.532
Carbonatoapatite	12.06	≡	4.684
Fluoroapatite	0.663	≡	0.26
Chloroapatite	4.397	≡	1.69
Hydroxyapatite	75.04	≡	29.90
Sodium	0.25	—	—
Loss on heating (other than CO <sub>2</sub> and H <sub>2</sub> O)	1.837	—	—
Total	97.202	37.066	16.986
Determined values (see Table I)	—	37.07	17.22

The loss in weight on ashing (4.62 %) represents the bound water, the greater part of the CO<sub>2</sub> and the organic matter. Assuming that the water is driven off from the hydroxyapatite to form oxyapatite a value (1.837 %) for the organic content can be obtained; this is probably not the true value. The protein content calculated from the N would be 0.98 %. The N value obtained by us was greater than that found by Sprawson and Bury [1928]. The utmost care was taken in the collection of the enamel. Blank determinations were made on the reagents and the recovery tested by distillation of standard (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> solutions.

#### *Dentine.*

The analysis of the dentine presented a difficulty because of its high organic (protein and fat) content. It is easy to remove the organic part by extraction but it is difficult to get quantitative recovery and so calculate back to the dry material. Calculating from the P content of the dry dentine and the loss in weight on ashing, it appeared that 0.4 % of the P is lost in the ashing process. It can be deduced from the N values that not all the organic matter is protein; fat extraction raises the Ca/P ratio; these two facts indicate that this loss of P is due to the presence of lipoid P and that no inorganic P is lost. Hence it was considered possible to use the values obtained on ashed dentine for the calculations dealing with the consideration of the composition.

#### *Consideration of the dentine results.*

Dentine differs from enamel in several respects (Table III). The former is devoid of chlorine; if the values for the ashed dentine are compared with those of the enamel it can be seen that dentine contains more Mg; the P content of dentine is also greater; this gives a lower Ca/P ratio, which does not correspond so closely to the ratio for apatite as does that of enamel. All the CO<sub>2</sub> was lost on heating, which was taken to mean that all was present as simple carbonate. We considered that all the Mg was present as MgCO<sub>3</sub> and assumed the rest of the CO<sub>2</sub> to be combined as CaCO<sub>3</sub>. In this way the following figures were obtained:

0.835 g. Mg (found)	2.922 g. MgCO <sub>3</sub> (dry dentine)	1.958 g. MgO (ashed).
1.645 g. CO <sub>2</sub>	3.738 g. CaCO <sub>3</sub> (dry dentine)	2.945 g. CaO (ashed).

Table III. *The composition of dentine.*

	Dry dentine	Ash of dentine
Ash %	71.09	—
Nitrogen %	3.43	—
Calcium %	27.79	39.83
Magnesium %	0.835	1.175
Sodium %	0.19	0.267
Potassium %	0.07 or less	0.1013
Phosphorus %	13.81	19.04
CO <sub>2</sub> %	3.176	Nil
Chlorine %	Nil	Nil
Fluorine %	0.0246	0.0346
Ca/P	2.012	2.091
Ca/Mg	33.29	33.90
P/CO <sub>2</sub>	4.349	—
Ca : P : CO <sub>2</sub> (molar prop.)	10 : 6.412 : 1.036	10 : 6.17 : 0

The Ca left in the ashed dentine was then 37.727% and this with a P value of 19.04% (Ca/P = 1.981) could not be present as apatite only. From the ratio of Ca/P, the possibilities are that the Ca and P are present as (1) Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> or (2) Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> + CaHPO<sub>4</sub> or (3) 3Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>.CaX + CaHPO<sub>4</sub>. The X-ray analyses have shown that dentine contains considerable quantities of apatite and hence the third possibility stated above seemed the most probable. Working on this assumption, the following figures were obtained: 11.67% CaHPO<sub>4</sub> and 58.03% of hydroxyapatite in dry dentine, due consideration having been given to the fluoroapatite. Table IV gives a complete account of the results of these calculations based on the analyses given in Table III above.

Table IV.

	Dry dentine %		Ashed dentine %	Ca in ashed dentine %	P in ashed dentine %
MgCO <sub>3</sub>	2.922	MgO	1.958	—	—
CaCO <sub>3</sub>	3.738	CaO	2.945	≡ 2.103	—
CaHPO <sub>4</sub>	11.67	CaHPO <sub>4</sub>	16.42	≡ 4.829	3.742
Hydroxyapatite	58.03	Oxyapatite	80.19	≡ 32.528	15.12
Fluoroapatite	0.663	Fluoroapatite	0.933	≡ 0.370	0.172
Sodium	0.19	Sodium	0.267	—	—
Organic matter	24.693	—	—	—	—
Total: (Calc.)	101.906	—	102.713	39.83	19.034
(Found)	—	—	—	39.83	19.04

It is realised that this treatment of the results is not the only possible one but after due consideration it seemed justifiable. Hydroxyapatite is the most abundant constituent of the dentine as it is of enamel. It is to be noted that the quantity of Mg in human teeth is considerably less than in the teeth of some other mammals and that the actual quantity is so small that it cannot replace Ca to any extent in normal teeth. Mg is now considered important for the activity of phosphatases and it may be that the significance of Mg in relation to teeth is in connection with the proper laying down of the Ca<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> complex rather than with the formation of part of the inorganic complex. No doubt when Ca is lacking Mg may be laid down in its place, but this is abnormal.

It is hoped that similar analyses of sound teeth showing hypoplastic structure and of carious teeth will throw some light on the problem of dental disease.

## SUMMARY.

1. Analyses of enamel and dentine of sound human teeth of good structure and of one type from a defined age group were made. The total ash, N, Ca, Mg, Na, K, P, CO<sub>2</sub>, Cl, F and Si were determined.

2. The compositions of the inorganic parts of enamel and dentine are not identical. Enamel consists mainly of apatite, the greater part of which is in the hydroxy form.

3. Dentine contains less apatite but more carbonate than the enamel. Not all the inorganic P of the dentine is in the form of apatite; CaHPO<sub>4</sub> is probably a constituent.

4. The CO<sub>2</sub> of the enamel is not all driven off by heating; that of the dentine is.

This work was carried out while one of the authors (J. H. B.) was in receipt of a grant from the Medical Research Council. We wish to record our thanks for this and for an expenses grant from the same source.

Our thanks are also due to E. W. Gildersleeves for assistance in the collection and preparation of the material for analyses.

## CCCXXV. THE VITAMIN D ACTIVITY OF CACAO SHELL.

### I. THE EFFECT OF THE FERMENTING AND DRYING OF CACAO ON THE VITAMIN D POTENCY OF CACAO SHELL.

### II. THE ORIGIN OF VITAMIN D IN CACAO SHELL.

By ARTHUR WILLIAM KNAPP

*(The Laboratories, Cadbury Bros. Ltd., Bournville),*

AND KATHARINE HOPE COWARD

*(Pharmacological Laboratory of the Pharmaceutical Society).*

*(Received October 29th, 1935.)*

### I. THE EFFECT OF THE FERMENTING AND DRYING OF CACAO ON THE VITAMIN D POTENCY OF CACAO SHELL.

THE authors have shown [1934] that one sample of the testa or "shell" of the ordinary dried fermented cacao beans from the Gold Coast had a vitamin D potency of 28 International Units (i.u.) per g. 10 months later another sample of cacao shell was examined by them and found also to contain 28 i.u. per g. As this is quite an exceptional potency for a vegetable product, further investigation was made with the object of determining whether the vitamin D was present in the seed or was produced during the preparation for the market.

The fruit of the cacao tree is a large pod, which contains about 40 cacao seeds or "beans". Cacao shell is the name given to the testa of the bean. It is covered with a layer of mucilaginous pulp which contains about 10% of reducing sugars and 0.7% of citric acid. In the approved method of preparation for the market the beans are put in a box and allowed to ferment. After fermentation the beans are dried until their moisture content is below 8%. They can then be kept without change.

The usual procedure for fermentation on the Gold Coast is to make a conical heap of the beans and cover them with plantain leaves. The method used in the experiment to be described is the more approved method using 3 wooden boxes arranged in steps. The beans are placed in the top box and turned into the lower one after 2 days. They are turned into the lowest box after a further 2 days and are thus fermented 6 days in all. Fermentation of the sugars occurs spontaneously, and the temperature rises, generally reaching 50° in 3-5 days according to the method used. The pulp, by loss of liquid, is diminished in bulk and becomes brown and less mucilaginous. In the later stages acetic and other bacteria develop and, under certain circumstances, moulds also.

During the fermentation of the pulp changes also occur in the interior of the seed. After 2-3 days' fermentation the seed dies. The two folded cotyledons which form the greater part of the seed are purple and, when they die, the purple substance originally in isolated cells becomes distributed throughout them. During the later stages of fermentation and during drying, the colour of

the inside of the bean, that is of the cotyledons, gradually changes from purple to brown owing to the oxidation of the tannins. A little of the tannins, along with the theobromine, also passes from the cotyledons into the shell, which as a result darkens in colour.

The fermented beans are spread out on trays or tables and dried by turning over and over in the sun. At least 6 days are required to dry the beans. The oxidation of the tannins continues as long as the beans are moist. Whilst the beans are damp mould may grow on the shell during the night.

It will thus be seen that the cacao bean normally undergoes two important operations: (1) fermentation in boxes or heaps and (2) drying. Most cacao is fermented and sun-dried, but some cacao is merely sun-dried, and some fermented cacao is artificially dried.

#### EXPERIMENTAL.

The authors decided to put on tests to determine the effect on the vitamin D content of (1) fermentation and (2) exposure to the sun in drying. The preparation of the cacao was carried out at Cadbury Hall, Kumasi, according to the instructions of one of us (A. W. K.), by Mr F. Nicholas, who is the officer in charge of the Gold Coast Agricultural Department Training Centre. The ordinary Gold Coast cacao belongs to the botanic species *Forastero Amelonado*. Only pods of this species were gathered for the experiment. They were taken from one plot in the plantation. On November 6th, 1934, a sufficient number of pods were collected to provide beans for all the experiments. The beans were extracted from the pods and were well mixed. Four portions of these were taken and submitted to the following treatment:

Sample 1. Beans dried at once in the dark.

Sample 2. Beans dried at once in the sun.

Sample 3. Beans fermented and then dried in the dark.

Sample 4. Beans fermented and then dried in the sun.

*Sample 1.* The beans *dried in the dark* were taken straight from the pod and dried on wooden trays in a water-oven. The temperature of the oven was maintained near, but did not exceed, 90°. The drying occupied 6 days. The temperature attained by the beans was sufficient to kill them. As a result the purple substance in the cotyledons was diffused. As the temperature in the early stages was not high enough to destroy the oxidase which is present, a certain amount of browning of the interior of the bean took place.

*Sample 2.* The beans *dried in the sun* were placed at first on a wooden tray and later on palm leaf matting. Owing to the hygroscopic nature of the pulp round the beans, after three weeks the drying was still far from complete. The pulp was thus a suitable medium for the growth of yeasts or mould. As it was feared that the development of mould in the damp mucilage might affect the results, it was decided to wash the beans and thus remove a considerable part of the mucilage. This was done and the beans then dried quickly.

*Sample 3.* The beans *fermented and dried in the dark* were subjected to the standard fermentation in boxes as described above. Part of them were dried in a water-oven in the same way as those in test 1. The temperature was maintained near, but did not exceed, 90° and drying was complete in 4 days.

*Sample 4.* The beans *fermented and dried in the sun* were the remaining part of the beans not used in preparing sample 3. They were dried in the normal way at first on wooden trays and later on palm leaf mats. The weather was not favourable and the drying took 22 days.

At the conclusion of the tests the beans were at once placed in tins. They were despatched to England in December 1934. The shells were carefully removed from the beans by hand, and ground to powder in a dark room.

The vitamin D content of the four samples of cacao bean shell was estimated by the method already described [1934]. The fourth sample (fermented and dried in the sun) was found to have a potency of the order of that of the previous samples examined, namely 21 i.u. per g. A preliminary test on samples 1, 2 and 3 showed that their potency was very much less than that of sample 4. The shell was, therefore, incorporated in the diet in order to give the rats a large enough quantity of it. Daily records were made of the amount of food eaten, and the amount of shell eaten was calculated. The diets of the rats for these three tests then consisted of:

	%
Yellow maize	60
Wheat gluten	16
Calcium carbonate	3
Sodium chloride	1
Cacao bean shell	20

The diet in its original form contained 1.37 % Ca and 0.34 % P. An analysis of the cacao bean shell showed that it contained 0.26 % Ca and 0.39 % P. The addition of 20 % shell to the rachitogenic diet therefore reduced the ratio Ca : P from 4 : 1 to about 3.4 : 1. This difference was not great enough to produce healing in the metaphyses of the rats under the conditions of our test [Key and Morgan, 1932].

The results of the tests on the four samples are summarised in Table I.

Table I. *Vitamin D in cacao shell.*

Shell	Treatment of beans	i.u. per g.
Sample 1	Dried in the dark 6 days	0
Sample 2	Dried in the sun more than 21 days; washed	0.6
Sample 3	Fermented and dried in dark 4 days	0
Sample 4	Fermented and dried in sun 22 days	21.0

## II. THE ORIGIN OF VITAMIN D IN CACAO SHELL.

In Part I we have described experiments which showed that vitamin D was not present in the shell of cacao beans which had been dried in the dark, whether fermented or unfermented. This indicates that the shell of the cacao bean as it comes fresh from the pod does not contain vitamin D, and yet after exposure to sunlight during drying, vitamin D was present in small amounts in unfermented shell and in very large amounts in fermented shell. Presumably a precursor of vitamin D was present in the shell and was converted into vitamin D by the active rays of the sun. Since the sun-dried, fermented shell was very much more active than the sun-dried unfermented shell, it was decided to carry the comparison further and irradiate both the shells which had been dried in the dark as nearly equally as possible, by exposure to the rays of a quartz mercury-vapour lamp.

### EXPERIMENTAL.

Equal weights (56 g.) of the two samples, very finely powdered, were spread evenly in separate galvanised zinc trays of 4 sq. ft. area. These were placed side by side and a quartz mercury-vapour lamp hung 2 ft. 6 in. immediately above the

middle of the space covered by the two trays. The lamp was run at 95 volts, 3.5 amps. In order to ensure equal irradiation of each sample, the trays were turned through an angle of  $180^\circ$  after 8 min. irradiation, and after another 7 min. the powder was collected and respread. The position of the two trays was interchanged. After 8 min. more, the trays were again turned through an angle of  $180^\circ$  and irradiation was continued for 7 more minutes. Thus the total duration of irradiation was 30 min. At the end of this time, there was no visible difference in the appearance of the two powders.

The vitamin D estimation of the two irradiated samples was carried out in the usual way. A little healing was shown in the rats which received the irradiated unfermented shell but as all of them had lost weight during the experiment (an average of 9.5 g.) in spite of having eaten an average of 5.1 g. food per day, the small amount of healing was easily accounted for and had to be disregarded. On the other hand, only one out of 15 rats which received the irradiated fermented shell lost weight, the rest gaining an average of 6.7 g. in the 10 days. A similar experience had been encountered in most of the rats used in testing samples 1 and 3.

The result of the test on the irradiated preparations is given below, together with the previous results for comparison:

Cacao beans used	Vitamin D in cacao shell.	I.U. per g.	
	Dried in the sun. Exposed to sun- light 22 or more days	Dried in the dark	
		Before irradiation	After irradiation
Unfermented	0.6	0	0
Fermented	21.0	0	10.0

It is evident that the process of fermentation has increased enormously the amount of the precursor of vitamin D present in the cacao bean shell.

#### DISCUSSION.

It will be noticed that the potency of the shell powder irradiated artificially is not as great as that of the cacao shells that had been exposed to sunlight. This could scarcely be expected as both the qualities and the intensities of the two sources of radiation were different. Neither process could be expected to bring about the maximum activation. Moreover, only the outside of the shell of the whole bean was exposed to the sun, whereas the powdered shell exposed to the ultraviolet rays from the lamp was spread so thinly that it is possible that the irradiation was excessive and had resulted in the destruction of part of the vitamin D just formed.

The temperature conditions and period of drying were also different. The solar radiation on the Gold Coast has a mean maximum temperature of  $63^\circ$  and at night the mean minimum temperature is in the region of  $23^\circ$ . The beans were exposed to these conditions for 22 or more days and nights. In the drying oven the temperature continuously approached but did not exceed  $90^\circ$ , the fermented beans being 4 days and the unfermented 6 days in the oven.

In neither case were the temperature conditions severe enough to affect the precursor, and although they might diminish any vitamin D present, they would not result in its complete destruction [Bourdillon *et al.*, 1932]. The absence of either precursor or vitamin D from the unfermented shell dried in the dark indicates that neither is present in the shell originally. Thus the formation of the

precursor of vitamin D is apparently an outcome of the process of fermentation. This process may affect the ergosterol content of the shell or it may not; it is certainly known to favour the growth of micro-organisms (notably yeasts) on the surface of the bean shells. Our theory is that the source of the precursor in the fermented bean shells is the mass of micro-organisms produced during the process of fermentation. This would account not only for the large amount of vitamin D formed on irradiating the fermented shell (either naturally or artificially) but also for the small amount found in the unfermented bean shell dried in the sun; for the periods in the sun were interspersed with cooler night periods during which yeasts could grow.

(a) *The development of the precursor is independent of place or method of fermentation.*

There is some indication that vitamin D is present in the shell of most kinds of fermented sun-dried *Forastero* cacao and that its presence is independent of the country of origin of the cacao. In the preparation of the cacao shell for certain feeding tests [Kon and Henry, 1935] over 1000 tons of roasted beans were de-shelled to obtain a representative sample. The beans consisted mainly of *Forastero* cacao, being a mixture of fermented and, for the most part, sun-dried cacaos from West Africa, the West Indies and South America. The cacaos had been purchased throughout the season. The vitamin D potency obtained by us for this mixture of cacao shells was identical with that obtained for the pure Gold Coast shell previously reported on, namely, 28 I.U. per g. That the precursor is produced by some action which is not peculiar to any one method of fermentation is indicated by the following results obtained from sun-dried cacao from the same producing area, namely, the Gold Coast. The sample previously reported on [1934] was from cacao fermented by the native farmers mainly in heaps, whereas the sample reported on in Part I of this paper was carefully fermented in boxes and regularly mixed. This gave a potency of the same order as, but lower than, that of the native-produced sample.

(b) *Relative potency of vitamin D in shell and interior.*

Manceau and Bigé [1931] have shown that in the seeds which they tested the sterols present in the outer layer (0.02–0.06 %) were slightly greater in amount than in the interior (0.017–0.05 %). Judging from the results of Labbé *et al.* [1929] there is a marked difference in the case of ordinary (presumably fermented) cacao seeds. There are present two sterols, A and B, both of which develop antirachitic properties on irradiation. The B sterol is identical with the ergosterol from brewer's yeast [de Balsac, 1933]. The quantities present are large: 6–8 % of the sterols in the fat from cacao shell and 0.30–0.40 % in the cacao butter from the cotyledons (or nibs). Assuming 54 % of butter in the nibs and 4 % in the shell, the figures would be 0.16–0.21 % sterols in the nib and 0.24–0.32 in the shell. The difference in vitamin D found by the authors [1934] is yet more marked; using Gold Coast cacao the nibs gave 1 I.U. per g. as compared with 28 I.U. for cacao shell.

Figures for the potency of vitamin D have been published for comparatively few foodstuffs. Amongst animal products, save for liver oils, it is rare to find 1 I.U. per g. exceeded, and in vegetable products the amounts recorded are so small that the cacao bean is unique in its vitamin D content both in the interior and in the shell. Whilst the wide differences between our vitamin D figures for nib and shell might be explained as due to the exposure of the shell to the sun,

the difference between the amounts of sterols in nib and shell needs further explanation, as does the striking difference in the vitamin D potencies of the shell of fermented and unfermented beans.

(c) *The production of the precursor of vitamin D.*

Below we consider some possible causes of the production of the precursor in the shell during fermentation.

(1) *Changes due to incipient germination and death of the cacao seed.* In the early stages of fermentation the temperature rises and the conditions are favourable to incipient germination. Little visible change occurs because within 60 hours from the beginning of the fermentation the germ is killed. Soon after the cotyledons also die. Little is known regarding the incipient germination but the changes that follow the death of the seed have received attention.

Tests for lipase have been made. Brill [1915] found none in either fermented or unfermented beans and Ciferri [1931] found lipase only in unfermented beans. The absence of lipase from fermented beans is in accord with practical experience of the good keeping properties of both cacao beans and cacao butter. During fermentation, after the death of the seed, certain substances pass from the nib to the shell, e.g. theobromine [Knapp and Wadsworth, 1924] and tannins [Whymper, 1933]. The fat obtained from the shell possesses a high percentage of the vitamin D activity of the shell [Kon and Henry, 1935] so that changes in the fat percentage are of interest. In our samples the fat percentages are lower after fermentation.

*Analyses of the shells.*

Sample	Shell on bean %	Moisture in shell %	Fat in shell. Light petroleum extract %
Unfermented (dried in dark)	12.9	3.3	1.4
Fermented (dried in dark)	10.8	6.3	1.1
Unfermented (dried in sun and washed)	6.5	8.8	1.7
Fermented (dried in sun)	12.9	8.3	1.2

As ergosterol is considered to be primarily a product of carbohydrate metabolism, the possibility of shell acquiring this from the cotyledons is small.

(2) *Changes in the pulp which may produce the precursor in the shell.* The unfermented pulp contains about 10% reducing sugars, the fermented pulp naturally contains less. Mere exposure of fruits which are rich in natural carbohydrate, e.g. dates, apricots, to the tropical sun, does not produce vitamin D [Lecoq, 1932].

The simplest explanation of the production of vitamin D in cacao shell is that it is due to yeast, which grows in the pulp on the outside of the bean during fermentation and is irradiated by the sun during drying.

Various investigators [Ciferri, 1931] have shown that in the early stages of fermentation *Endomyces anomalus* and members of the *Saccharomyces apiculatus* group (e.g. *Klockeria cacaicola*) are the most common organisms present, although *Eutorulopsis theobromae* is also to be found. The latter yeast is fairly common throughout fermentation, but in the later stages the most abundant are *Torulopsis Lilienfeld-Toalii*, *Saccharomyces ellipsoideus* and *Schizosaccharomyces Bussei*. The last two survive both fermentation and drying and are found on practically all kinds of commercial cacao beans [Lilienfeld-Toal, 1927]. From fermenting cacao on the Gold Coast, Dade has isolated a new *Mycotoruloides*, a *Klockeria*, a *Hansenula* and a *Mycoderma* [Knapp, 1935]. It may be well to com-

plete the list of micro-organisms which may be found on the shell. As the fermentation continues acetic acid is formed to a greater or less extent, and Eckmann [1928] has shown that on cacao beans from all countries acetic bacteria can be found, e.g. *B. xylinum*, *B. xylinoides*, *B. orleanense* and *B. ascendens*.

In well conducted fermentations the beans are turned at intervals from one box to another to mix and aerate the mass. On the Gold Coast the farmer sometimes fails to give his heap a single turning or mixing. In this case by the fifth day certain moulds will be present, particularly the thermophiles, *Aspergillus fumigatus* and *Mucor Buntingii* [Bunting, 1928]. During drying certain other moulds may grow on the shell of the bean: aspergilli, mucors or penicillia, particularly *A. flavus*, *A. tamaris*, *A. niger*, *A. glaucus* and *A. sydowi*. If drying is continued these will cease to grow and will become no longer readily visible to the eye.

Of the micro-organisms concerned in cacao fermentation, the acetic bacteria can presumably be ignored as a source of ergosterol. Certain specific moulds have been shown to synthesise ergosterol. This is found in the dried mycelia [Birkinshaw *et al.*, 1931] and on irradiation moulds acquire anti-rachitic properties [Preuss *et al.*, 1931].

The appearance of mould on cacao during drying depends on the weather conditions and on the care taken. Given bad conditions or carelessness it may appear on the shell of either fermented or unfermented beans. The moulds recorded in both cases are for the most part of the same species. The irregular incidence of mould would not account for the regularity of the vitamin D found in the shell of fermented beans. We conclude that mould is a relatively unimportant source of the precursor of vitamin D in cacao shell.

The presence of yeast explains the observed facts better. If cacao is put in a box and allowed to ferment, the pulp shows great numbers of yeast cells after one day and the numbers are maintained for several days. Ciferri gives the number of mould spores on healthy fermented cacao as being about 1000 per bean: according to Dade the number of yeast cells during fermentation is of the order of 2000 millions per bean. When unfermented beans are spread in a layer to dry, yeast develops on the first day, but later conditions are not continuously favourable to its growth. In our experiments, as sometimes occurs in normal practice to facilitate sun drying, the unfermented beans were washed. This removed much of the pulp and with it much of the yeast present.

Yeast cells occur in quantity on the normal dried fermented bean, often as large colonies. They are also present in quantity on beans which have not been deliberately fermented but have been dried in the sun. They cannot be washed off and counted as they are distributed throughout the dried pulp layer of the shell. An attempt was made in the experimental samples to get some idea of the quantity of yeast cells by soaking and scraping off the surface of the shell. The unfermented beans whether dried in the dark or dried in the sun (and washed) showed very few yeast cells. The fermented beans in both cases showed a vast number, the greater number being present on the beans dried in the sun.

The capacity of the tropical variety of *S. ellipsoideus*, or of other cacao yeasts, for elaborating ergosterol is not known, but ordinary *S. ellipsoideus* in the dry state contains an average amount of ergosterol for a yeast, namely 0.6% [Bills *et al.*, 1930].

One of us [Coward, 1933] has reported the anti-rachitic activation of yeast by exposure to strong sunlight. The thin layer of yeast on the surface of the shell is well placed for efficient irradiation during drying.

Steenbock *et al.* [1930] and Kon [1931] by irradiating distiller's yeast have

raised its anti-rachitic potency to approximately 75 times that of a good cod-liver oil, whilst the yeast produced by Steenbock *et al.* [1930] for feeding cattle had a potency of 2700 I.U. vitamin D per g. Taking the latter potency as one not difficult to attain, about 1% of irradiated yeast on the shell of the cacao bean would give the figures 21 and 28 which we obtained for the fermented cacao. In the case of the unfermented beans dried in the sun the limited fermentation and the washing away of a good part of the pulp resulted in a figure of only 0.6 units. The conditions for the drying of beans taken straight from the pod and dried in the dark did not permit of the growing of yeast and hence with these we found no vitamin D after irradiation.

The growth of yeast in the pulp, combined with the exposure to the sun, satisfactorily accounts for the vitamin D in shell.

Both the vitamin D and the sterols in the cotyledons are unusually high. The manner of their production requires further investigation.

#### SUMMARY.

1. It is improbable that either vitamin D or ergosterol is present in the fresh shell of the cacao bean.
2. During fermentation, yeast containing ergosterol develops in the pulp on the shell.
3. During drying in the tropical sun the ergosterol is converted into vitamin D.
4. Hence the order of vitamin D potency of the shell of the cacao bean is: (1) artificially dried—absent; (2) not deliberately fermented but slightly fermented during sun-drying—fairly high, approaching the potency of dairy butter; (3) fermented and sun-dried—very high, twenty or thirty times the potency of dairy butter.

Our thanks are due to Mr F. Nicholas for carrying out the preparation of the samples listed in Part I.

# CCCXXVI. THE DETERMINATION OF VITAMIN A BY MEANS OF ITS INFLUENCE ON THE VAGINAL CONTENTS OF THE RAT.

BY KATHARINE HOPE COWARD, MARJORIE RUTH CAMBEN  
AND EVA MAUD LEE.

*From the Pharmacological Laboratory of the College of the Pharmaceutical  
Society.*

*(Received October 31st, 1935.)*

EVANS AND BISHOP [1922] first showed that when young rats were fed on a diet deficient in vitamin A, the cyclic changes in the vagina were apparently upset, for "cornified cells" (keratinised cells) were found continuously day after day in the vagina. If vitamin A was given the condition was cleared up and the regular cycles became easily recognised. Evans and Burr [1928] showed that the oestrous cycles occurred naturally during the period when keratinised cells appeared continuously but the signs of the cycles, as usually given by the vagina, were hidden.

Other workers have confirmed the findings of Evans and Bishop, and Baumann and Steenbock [1932] showed that this evidence of vitamin A deficiency responded to treatment with daily doses of carotene in Wesson oil (hardened cottonseed oil). They suggested that this symptom of vitamin A deficiency and its cure by the giving of vitamin A might be made the basis of a method for the quantitative estimation of vitamin A.

The suggestion was very attractive to us as this response of the animal appeared to be specific for vitamin A. (Methods based on the growth response of animals are open to many well-known criticisms.) It also seemed possible that this method might offer a means of estimating the vitamin A potency of a preparation suspected of being labile, for it might be possible to obtain measurable results from giving one dose only of the preparation to each rat suitably prepared. This has proved to be possible. A logarithmic curve has been obtained relating (a) the number of days elapsing before cornified cells disappeared from the vagina, and (b) the size of the dose given. The duration of the cure obtained by giving vitamin A also bears a curvilinear relationship to the dose given, but this curve is not logarithmic.

## METHOD.

(a) *General scheme of the test.* The only information available as to the sensitivity of the vagina to doses of vitamin A was given by Baumann and Steenbock [1932] who had found that 10 $\gamma$  carotene per day restored dioestrous smears within a week. Klusmann and Simola [1933] found that daily doses of 1–5 $\gamma$  carotene caused the cornified cells to disappear. None of these workers stated exactly what condition the rats were in when doses were first given. We therefore had to determine exactly what criteria we would use (a) to consider a rat ready for the test and (b) to consider a rat to have responded to a dose of vitamin A. It is, of course, unnecessary for workers in different laboratories to adopt the same criteria for biological reactions provided that a standard of reference is available

in terms of which an estimation can be made, and provided also that the workers in different laboratories have shown that they can obtain, by means of their own technique, a graded response to graded doses of the purest form available of the active substance.

To consider a rat ready for the test, we decided that it must have had cornified cells (almost exclusively) in the vaginal smear daily for 10 days. As the rats' reserves of vitamin A become exhausted, these cells appear suddenly in very large numbers and with only slight admixture with leucocytes or none at all.

To consider a rat to have responded to a dose of vitamin A, we decided that cornified cells should be completely absent from the smear or present in very small numbers, not more than a stray group of perhaps half a dozen in the whole smear taken.

(b) *The preparation of the rats.* The vaginal contents of each rat which had attained a weight of 130 g. on a diet containing only moderate amounts of vitamin A were examined daily by Evans's simple method of removing a little of the material from the vagina with a small spatula and examining it at once in a drop of tap water under the low power (2/3) of a microscope. By the time that it was ascertained that cycles were occurring normally the rat had usually attained a weight of 140 g. It was then given the vitamin A-free diet in general use in this laboratory until the vaginal smear had contained cornified cells for 10 consecutive days. The rat was then considered ready for the test.

(c) *Dosing of the rats.* As the rats became ready for the experiment they were distributed among 7 groups of 10–12 rats per group. All the rats of any one group were given the same dose of cod-liver oil. On the day when they were considered ready the rats of the different groups were given in a single dose on one occasion 5, 10, 20, 40, 60, 100 and 200 mg. respectively of an average sample of cod-liver oil. The same vitamin A-free diet was continued, and the vaginal contents were examined daily. When the smear contained no cornified cells or only perhaps half a dozen of those cells, the rat was considered to have responded to the dose of cod-liver oil. The number of days elapsing between giving the dose and getting the response was considered the result. One rat in the whole series responded the day after dosing; that was estimated as 1. When a rat's smears contained cornified cells for 2 days after dosing, and was free from them on the third day, the response was estimated as 3. The longest interval noted between dosing and response was 10 days. Some of the rats given the lower doses of cod-liver oil did not respond at all though smears were taken for as many as 20 days after dosing. Some of them died without giving any response. For the purpose of averaging results the figure 10 was therefore given to each rat that did not respond within 10 days.

#### *The curve of response.*

The averages of the results from the animals in the different groups were taken as the responses to the different doses of cod-liver oil (Table 1). When plotted against the respective doses the results gave a curve in which only the two lowest doses were somewhat irregularly placed (Fig. 1). That the curve is logarithmic may be seen from Fig. 2 in which the average responses of the groups are plotted against the logarithms of the doses of cod-liver oil given. The best straight line through these points was calculated as  $y = 13.2 - 4.5x$ . Thus the curve relating the average responses of the groups of rats to the dose of vitamin A given is represented by the equation  $y = 13.2 - 4.5 \log x$ .

It is interesting to note that this curve of response is logarithmic although it is in no way a growth curve.

Table I. *Response of rats to a single dose of cod-liver oil shown by changes in the vaginal contents.*

Dose of cod-liver oil (Z). mg.	No. of rats on test	Interval between first dose and first appearance of leucocytes. Days	Interval between first day of cure and day when ready for second test, <i>i.e.</i> duration of cure.* Days	No. of rats which reached this stage
5	10	9.3	11.0	3
10	9	10.0	—	0
20	10	7.0	16.8	6
40	10	5.7	18.6	7
60	10	5.3	19.8	9
100	10	4.0	24.7	9
200	12	2.9	45.0	9

\* The interval between the first day of cure and the day when ready for second test includes (a) the time during which normal cycles were occurring and (b) the 10 successive days of cornified cells in the vagina which were regarded as the indication that the rat was ready for a second test.

Fig. 1. Curve of response relating the dose of vitamin A to the time taken to restore the normal condition of the vaginal contents.

Fig. 2. Curve of response relating the logarithm of the dose of vitamin A to the time taken to restore the normal condition of the vaginal contents.

*Duration of cure from a single dose of cod-liver oil.*

Vaginal smears of the rats which had been used for obtaining the curve of response already described were still taken daily to determine when each rat might be considered ready for another test; that was when a rat had again had cornified cells in the vagina for 10 successive days. For this measurement the rats which had not responded to the first dose within 10 days were, of course, ignored. The rats that had responded to the lower doses of cod-liver oil had at least one cycle before cornified cells again appeared continuously in the vagina. The rats that had received the largest dose of cod-liver oil had 6 or 7 cycles before cornified cells appeared continuously and obliterated them.

The time taken by a rat to become ready for a second test was reckoned as the interval between the first day of its cure from the first dose and the day when it had again shown cornified cells for 10 successive days. The averages of the times taken by the rats in the different groups were plotted against the respective doses of cod-liver oil given. If the 10 days of continuous cornification (regarded as the indication that the rat was ready for a second test) are subtracted from each of these averages, the remainder may be regarded as the duration of the cures. The response is plotted in Fig. 3. The curve is not logarithmic. It is quite clear that

Fig. 3. Curve of response relating the dose of vitamin A to the "duration of the cure" of the condition of the vaginal contents.

not only does the size of dose influence the rapidity of the response, but that it also influences the duration of the rat's resistance to a subsequent shortage of vitamin A.

*The possibility of using the same rats for several tests.*

Rats which had responded to a dose of cod-liver oil once were, when again ready, given a second dose of cod-liver oil equal to the first; the responses were measured in the same way. There were fewer rats available for the second test than for the first because several rats given the lower doses in the first test had not responded and were therefore not comparable with those which had responded and been again depleted. In each group one or two rats showed greater sensitivity in the second test than in the first, but most were apparently less sensitive, and it was necessary to compare averages. For the purpose of these

comparisons therefore, averages of the first test results were recalculated from those rats only which were used in the second test (Table II).

Table II. *Comparison between first and second tests of the same doses of cod-liver oil given to the same rats.*

The figures in this table were compiled from those rats only which survived for the second test.

Dose of cod-liver oil (Z). mg.	No. of rats given a second dose	Time required for response		Duration of response		No. of rats that sur- vived the 2nd test
		In 1st test. Days	In 2nd test. Days	In 1st test. Days	In 2nd test. Days	
5	3	8.0	No response	11.0	—	—
10	0	—	—	—	—	—
20	6	5.0	7.7	10.5	16.5	2
40	7	3.9	8.3	17.5	14.0	2
60	9	4.8	8.2	18.0	17.3	3
100	9*(8)	4.0	5.4	25.2	18.5	6
200	9	3.2	4.0	45.0	40.7	9

\* One of these died 3 days after receiving the dose.

On the whole the rats took a longer time to respond to the second dose of cod-liver oil than to the first, and in the groups containing a reasonable number of animals, the duration of cure following the second dose was shorter than the cure following the first. Another indication of the lessened sensitivity of the rats is the fact that of the 42 rats which responded within 10 days to the first dose, 20 did not respond within 10 days to the second dose. Thus under the conditions adopted for this test, estimations of vitamin A activity would apparently have to be made entirely on rats used thus for the first time or entirely on rats used thus for the second time. There should be no indiscriminate use of any rats which happened to be ready when needed. It is possible, however, that some modification of the test (such as the adoption of 5 successive days of cornification instead of 10 as the criterion for considering a rat ready for a test) might prevent the lessening of the sensitivity of the rats, but there is no evidence in these results to indicate that it would do so.

As there were only 22 survivors of the second test (rats which completed 10 successive days of cornification after their second cure), no third test was attempted.

#### *Weights of rats during the test.*

Only 6 rats out of 62 lost as much as 10 g. in weight during the period of feeding on the vitamin A-deficient diet, up to the end of the first 10 days when cornified cells appeared daily in the vagina. This is, therefore, an earlier symptom of vitamin A deficiency in adult rats than loss of weight, and is similar to Evans's experience with young growing rats. Of the 22 rats which survived the second duration test, 4 lost at least 10 g. in weight before their second period of 10 successive days of cornification was completed.

#### *Accuracy of the test.*

As a response which varies in magnitude and which can be measured gives a more accurate result than a simple "all or none" response, no calculations were based on the number of rats which were or were not cured within a given time.

The two groups of rats given the lowest doses of cod-liver oil could not be used for estimating the accuracy of the test, as in one of them, 7, and in the other 10 did not respond at all. Using the figure 10, the maximum and only value assigned to these, would therefore give a false idea of the accuracy of the

result, as in one group there would be no variation at all, and very little in the second. In the three groups given the next highest doses, there were 4, 3 and 1 rats respectively that did not respond. These 8 rats obviously cannot be excluded from the calculation, but their inclusion at the value of 10 each will bring a lower value for the standard deviation than the true value for the test. The total number of rats from which the calculation could then be made was lamentably small, viz. 52, distributed in five groups. The value of  $\sigma$  obtained from these is 2.86, whence the probable error of a result obtained with 10 rats is +36.2 or -26.4 % which is slightly greater than that obtained in a 3 weeks' growth test on young female rats in the same laboratory.

It must, however, be recognised that this figure is obtained from a calculation with a very small number of rats and, moreover, there may be other ways of measuring the effects that would give more accurate results.

#### SUMMARY.

Changes in the vaginal contents of the rat brought about by withholding vitamin A from the diet, and the restoration to the normal condition brought about by the giving of vitamin A, have been made the basis for a quantitative method of estimation of vitamin A.

The occurrence of keratinised cells for 10 successive days in the vagina was taken as an indication of the exhaustion of the rat's reserves of vitamin A. The disappearance of these cells from the vagina was taken as an indication of "cure". These criteria have been applied to the estimation of the vitamin A content of one dose only of the vitamin A-containing substance, that dose being given on the tenth day of the period of continuous cornified cells in the vagina.

The relation between the dose given and the mean number of days elapsing between the giving of the dose and the disappearance of cornified cells from the vagina is curvilinear. The curve is logarithmic in shape.

The duration of the cure effected by one dose of vitamin A, i.e. the time elapsing between the day when the cornified cells disappeared and the day when cornified cells had again appeared continuously for 10 successive days, also bears a curvilinear relation to the dose of vitamin A given, but this curve is not logarithmic.

The accuracy of this method of estimation appears to be somewhat less than that obtained by the criterion, increase in weight in 3 weeks of female rats which have been given daily doses of vitamin A after they had ceased to grow on a diet deficient in that factor.

# CCCXXVII. THE OXIDATION PRODUCTS OF THE UNSATURATED ACIDS OF LINSEED OIL.

By LESLIE CHARLES ALFRED NUNN  
AND IDA SMEDLEY-MACLEAN.

*From the Biochemical Department, Lister Institute.*

*(Received October 30th, 1935.)*

THE effect of the addition of linseed oil to a fat-free diet was the subject of an investigation in which one of us was co-operating and the chemical examination of the particular sample of oil was therefore undertaken. This examination has not yet been completed but in view of the communication of Green and Hilditch [1935] on the identification of linoleic and linolenic acids, it seems desirable to set forth the results at which we have so far arrived.

Green and Hilditch compared the effects of oxidising  $\alpha$ - and  $\beta$ -linoleic acids with potassium permanganate solution using Hazura's conditions [1888] and found that whereas from 4.8 g.  $\alpha$ -linoleic acid they obtained of the two tetra-hydroxy-acids 1.3 g. (M.P.  $173^{\circ}$ ) and 2.6 g. (M.P.  $155^{\circ}$ ) together with 1.1 g. of a viscous material, from  $\beta$ -linoleic acid only very small amounts of crystalline products were obtained, the main product being an oil (i.v. 13.7: equiv. wt. 76). They concluded that the  $\beta$ -acid had undergone profound disruptive oxidation under the conditions described by Hazura. In the course of the present investigation we had arrived at a somewhat similar conclusion since some form of labile tetra- or hexa-hydroxy-acid must have been formed and have undergone oxidative degradation to smaller molecules.

The linseed oil (i.v. 174) was saponified by alcoholic KOH, the free acids (245 g.) separated into saturated and unsaturated acids by the solubility of the lead salts in alcohol and the 226 g. unsaturated acid (i.v. 207) oxidised in portions of 7.5 g. using 1% alkaline permanganate under Rollett's conditions [1909] but keeping the vigorously stirred solution at a temperature of  $0-5^{\circ}$ . The cooled permanganate solution was added during a period of 25 min. and after standing for 10 min. the solution was decolorised by  $\text{SO}_2$  and left overnight at  $0^{\circ}$ . The white precipitate of hydroxy-acids was filtered off, dried and extracted with benzene, which dissolved 12.5 g. acids. The filtrate was steam-distilled, concentrated to 250 ml. and cooled overnight. A sticky yellow precipitate separated (C) and the filtrate on further concentration deposited a brown oil (F): by continuous ether extraction of the residual filtrate, more oil and a few white crystals were obtained.

From the first precipitate the dihydroxy-acid (A) was separated by its insolubility in boiling water and purified by recrystallisation from alcohol: the filtrate on cooling deposited mainly the tetrahydroxy-acids (B) and a mixture of tetra- and hexa-hydroxy-acids remained in solution, from which treatment with a limited amount of boiling water extracted a further amount of hexa-hydroxy-acid (D) and left in solution a mixture of the tetra- and hexa-hydroxy-acids (E). Fractions (B) and (C) were purified by repeated recrystallisation from 96% ethyl alcohol; the chief constituent of (B) was sativic acid, of (C) isolinusic acid. Fraction (D) consisting mainly of linusic acid was recrystallised from butyl alcohol. Fraction (E) was first extracted with boiling water by which a further quantity of linusic acid was separated and the remainder repeatedly recrystallised from ethyl alcohol. The volatile acids were isolated by steam-distillation, but the distillation was stopped before the acids had been completely separated.

The proportions of products actually isolated are shown in Table I.

*Determination of constitution of degradation products.*

The brown oil (F) contained a trace of manganese; it was insoluble in ether but readily soluble in 96% alcohol. After leaving for six weeks in an evacuated desiccator its weight was approximately constant; it showed no tendency to gain in weight, so oxygen was not being absorbed, but it became more viscid and darkened very much in colour.

Found: July 31st, C 59.71, 59.5%; H 8.14, 7.96%. Sept. 2nd, C 60.0%; H 7.77%.  $C_{12}H_{22}O_6$  requires C 55.96%; H 8.40%.  $C_{12}H_{20}O_6$  requires C 59.02%; H 8.19%.

When a small amount was titrated with alkali in the cold an equivalent weight of 350 was indicated but on warming the final end-point agreed with an equivalent of 181. The deep colour of the solution prevented good end-points being obtained.

Treated with zinc carbonate and cold water, a small proportion of a soluble zinc salt was obtained which was less soluble in hot water and separated out on heating the solution.

Found: zinc salt, C 45.51; H 6.31; Zn 20.0%. Equivalent of acid = 131.  $C_{12}H_{22}O_6Zn$  requires C 44.3; H 6.15; Zn 20.0%. Equivalent of acid = 131.

The zinc salt was therefore the salt of a dibasic acid  $C_{12}H_{22}O_6$ . The position of the hydroxy-groups was determined by oxidation with lead tetraacetate solution according to the method introduced by Criegee [1931] for the identification

of glycols: a small amount of azelaic acid was separated from the product. It appeared therefore that oxidation of a tetra- or hexa-hydroxy-acid had taken place at the 12-13 linkage and that two hydroxyl groups had been added at the 9-10 linkage. From the behaviour of the original oil on titration it seemed probable that most of the oil present was in the form of the lactonic acid  $C_{15}H_{20}O_5$ , the 9-hydroxyl group being in the  $\gamma$ -position to the carboxyl group.

The zinc salt when treated with lead tetraacetate in acetic acid solution at  $37^\circ$  gave a titration corresponding with the presence of about 27 % of the dihydroxy-dibasic acid: it is possible that this low percentage may be due to the formation of the relatively stable lactone so that the reaction was not complete.

*Determination of the constitution of the hydroxystearic acids.*

Since the hydroxy-derivatives of the higher unsaturated acids are crystalline compounds capable of purification by recrystallisation, they appear to be particularly suitable compounds in which to determine the position of the ethylenic linkage in the original unsaturated acids. The method of Criegee [1931] was therefore applied to determine the position of the adjacent hydroxyl groups. Both dihydroxystearic and sativic acids reacted almost quantitatively with the lead tetraacetate reagent at  $37^\circ$ . In both cases azelaic acid was isolated from the product and identified by a mixed melting-point with a specimen of pure azelaic acid (M.P.  $106-107^\circ$ ). Efforts to prepare the 2:4-dinitrophenylhydrazones of the aldehydes simultaneously formed failed in the presence of acetic acid since even moderately dilute acetic acid decomposed them forming the acetyl derivative of 2:4-dinitrophenylhydrazine. The solution of the aldehydes in glacial acetic was therefore diluted and extracted with ether and the ethereal solution shaken with a solution of sodium carbonate. The aldehydes were then converted into the hydrazone derivatives and these analysed, and identified; from sativic acid, *n*-hexaldehyde dinitrophenylhydrazone, M.P.  $97-100^\circ$ ; from dihydroxystearic acid, *n*-nonaldehyde dinitrophenylhydrazone, M.P.  $106-106.4^\circ$ .

From sativic acid a small amount of a deep red hydrazone was also isolated melting about  $200^\circ$ , possibly the dihydrazone of malonic dialdehyde. Oxidation of the aldehydes from the oxidation of sativic acid gave, besides *n*-hexanoic acid, a small amount of crystals, M.P.  $125-127^\circ$  (M.P. malonic acid  $133^\circ$ ). The positions of the ethylene linkages in linoleic acid between the 9-10 and 12-13 carbon atoms were therefore confirmed.

Hazura [1888] observed that with dilute solutions of permanganate, which were however stronger than those which we employed, only small amounts of azelaic acid were isolated: with increasing strength of permanganate solution the quantity of dibasic acid separated was greater. So far we have failed to identify normal dibasic acids among the oxidation products, probably owing to the greater dilution of the permanganate solution used. The ethylenic linkage in the 12-13 position was more readily broken than that between the 9-10 carbon atoms, since an 11-carboxy-9:10-dihydroxyundecanoic acid was isolated.

**SUMMARY.**

1. From the product of the oxidation of the unsaturated acids of linseed oil with  $KMnO_4$  in dilute solution a dibasic acid  $C_{15}H_{22}O_6$  has been isolated as the zinc salt, and its constitution determined as 11-carboxy-9:10-dihydroxyundecanoic acid. A considerable proportion of the corresponding lactonic acid appeared to be also present.

2. Labile forms of the hexa- and especially of the tetra-hydroxystearic acids seem to have been formed as products of the oxidation, readily suffering further degradation.

3. The method of Criegee was applied to determine the position of the hydroxyl groups of sativic and dihydroxystearic acids, and of the acid  $C_{12}H_{22}O_6$ .

# CCCXXVIII. MAINTENANCE NUTRITION IN THE PIGEON. THE INFLUENCE OF DIETARY PROTEIN AND VITAMIN B<sub>3</sub>.

BY CYRIL WILLIAM CARTER AND JOHN RICHARD O'BRIEN.

*From the Department of Biochemistry, Oxford.*

*(Received November 1st, 1935.)*

THE multiple deficiencies inherent in an exclusive diet of polished rice have for some time been recognised as being contributory to the syndromes of human beriberi and avian polyneuritis. In addition to a deficiency in certain vitamin factors in polished rice the adequacy of the protein intake on such a diet has been questioned by several workers who, when studying the vitamin requirements of birds, made use of synthetic diets with caseinogen as the source of protein [Sugiura and Benedict, 1923] and daily supplements of meat protein to a polished rice diet [Block *et al.*, 1932], or autoclaved whole wheat [Morris, 1933]. The effect of a deficiency of protein has been demonstrated by Carter [1934] who found that pigeons on a polished rice diet supplemented by a concentrate of vitamin B<sub>1</sub> and the fat-soluble vitamins failed to regain their maximum weight after a short period of depletion, whereas the addition of caseinogen sufficed to ensure full weight recovery. These observations did not completely agree with those of O'Brien [1934] who in the course of an investigation on the nature of vitamin B<sub>3</sub> found that a caseinogen supplement to such a diet promoted an initial gain in weight but failed to restore maximum weight. An extract of hydrolysed wheat germ containing vitamin B<sub>3</sub> and the hydrolytic products of wheat proteins always induced a gain in weight comparable with that seen in birds on a whole wheat diet. The experience of these workers suggests that at least two factors are playing a part in the partial weight restoration of pigeons on a diet of rice supplemented with vitamin B<sub>1</sub> concentrates; (a) a lack of protein and (b) vitamin B<sub>3</sub> deficiency. In this paper experiments are recorded which throw further light on this hypothesis.

It seemed to us possible that the severity of the initial depletion of the stored vitamins might determine the subsequent response to caseinogen. In those birds which retained much of their original store of vitamin B<sub>3</sub> as a result of a short period on polished rice the addition of vitamins B<sub>1</sub> and B<sub>3</sub> together with caseinogen should ensure a full recovery to maximum weight. On the other hand birds submitted to a more prolonged régime of polished rice involving severe loss of weight might be expected to be deprived of much of their stored vitamin B<sub>3</sub>, and consequently would only regain their maximum weight if this factor, in addition to those mentioned, were also included in the diet. No precise information as to the period required to deplete the pigeon of vitamin B<sub>3</sub> is available although Carter *et al.* [1930] suggested that this might exceed 30–35 days. The experiments here described substantiate these views. It has been observed that birds on a polished rice diet supplemented with vitamin B<sub>1</sub> concentrates showed marked gains in weight when given protein in the form of caseinogen or gluten. These gains in weight are, however, appreciably influenced by the preliminary

degree of vitamin depletion. In this connection it may be mentioned that the extent of the initial loss in weight is a more reliable guide to the severity of the depletion than the duration of this depletion. In those cases where the degree of depletion is considerable a failure to reach maximum weight is seen but can be remedied by the administration of vitamin B<sub>3</sub> concentrates in the form of extracts of plant and animal tissues, particularly of liver and wheat germ.

#### EXPERIMENTAL.

##### *Method.*

The birds under test were caged singly under conditions which have been previously described. Their basal diet consisted of washed and autoclaved polished rice (95 %), McCollum's salt mixture (5 %) and a small amount of grit in the form of oyster shell. Every alternate day they were given cod-liver oil (10 drops). The source of vitamin B<sub>1</sub> was an alcoholic concentrate from activated norite [Kinnersley *et al.*, 1933] which contains, in addition to vitamin B<sub>1</sub>, vitamin B<sub>5</sub> and vitamin B<sub>6</sub>. Throughout this communication when speaking of vitamin B<sub>1</sub> concentrates we refer to this impure concentrate. The daily dose of this concentrate was equivalent to 10–12 pigeon day doses of vitamin B<sub>1</sub> (11.1 pigeon day doses equal approximately 1 I.U. [Kinnersley and Peters, 1935]). Caseinogen (Glaxo, alcohol-extracted) and wheat gluten (Harrington) were not further purified and were administered in dry form. When the birds received more than one supplement the different doses were given at intervals of not less than 2 hours.

Varying degrees of depletion of the stored vitamins were effected by allowing the birds to feed *ad libitum* on the basal diet for different periods before giving them additional supplements.

##### *Effect of vitamin B<sub>1</sub> concentrate.*

The typical response of pigeons receiving daily doses of the vitamin B<sub>1</sub> concentrate after a period of depletion on the basal diet is a rise in weight which, although rapid for a few days, reaches a plateau substantially below the maximum level for the bird. No further rise in weight is observed if the dose of the concentrate is increased to as much as 60 doses per day. This fact has now been well established. From a study of the influence of the duration of depletion on the weight response of the pigeon to vitamin B<sub>1</sub> concentrates alone some evidence has been obtained of the need of a further factor or factors.

The duration of the initial depletion appears to influence the subsequent response in weight change to the vitamin B<sub>1</sub> concentrate. 43 birds received daily 12 doses of the vitamin concentrate after an initial depletion period the duration of which varied from 14 to 34 days. In the short depletion group the body weight did not fall below 70 % of the maximum (Group 1), whereas in the long depletion group the weight declined below 70 % of the maximum (Group 2). The average gain in weight for birds of Group 1 is 57 g. as compared with 35 g. for those of Group 2. Further, if the vitamin concentrate is administered for a lengthy period the weight plateau is not always maintained but may be succeeded by a very slow decline, which in some cases may result in almost complete relapse to the original depletion weight (Fig. 1). In a series of 10 birds 12 doses of the concentrate were given daily for periods of 106–201 days. Whereas the average maximum gain of weight amounted to 76 g., the average nett gain over the whole period was only 52 g. In two cases, it was observed that the earlier rise in

weight was followed by a slow fall which actually resulted in a final nett loss. In other birds this decline is present though much less conspicuously, and one bird showed an exceptionally large initial rise with practically negligible decline later.

Fig. 1. Illustrates the response of birds on polished rice to various supplements. At A, 12 doses of vitamin B<sub>1</sub> concentrate; at B, 12 B<sub>1</sub> + 2 g. caseinogen; at C, 12 B<sub>1</sub> + 2 g. caseinogen + vitamin B<sub>3</sub> concentrate were administered.

*Effect of vitamin B<sub>1</sub> concentrate supplemented with protein.*

Determination of the daily rice intakes of pigeons fed on the basal diet supplemented with vitamin B<sub>1</sub> with and without added protein have been compared with the intakes of these birds on whole wheat. The data summarised in Table I show that polished rice as a basal diet satisfies the caloric requirements

Table I. *Calorie and protein intake on rice and whole wheat.*

No. of birds	Nature of diet	Av. daily food intake g.	Av. daily calorie intake Cals.	Av. daily protein intake g.	Days on test
8	Rice + vitamin B <sub>1</sub> concentrate	26.7	96.5	1.72	23-27
8	Rice + vitamin B <sub>1</sub> concentrate and gluten	21.1	85.6	3.37	42-50
6	Rice + vitamin B <sub>1</sub> concentrate and caseinogen	21.2	86.0	3.38	14-50
5	Whole wheat	30.8	105.9	3.36	21

under our conditions. It is seen that the consumption of polished rice by a bird suffices to give an intake of 85-95 Cals. per day; that of whole wheat 105 Cals. These figures agree satisfactorily with the values of Sugiura and Benedict [1923] of 70 Cals. per day, and of Block *et al.* [1932] of 52-93 Cals. per day for normal maintenance. In the present case the significance of the difference in the caloric intake of birds on rice and whole wheat is minimised by the fact that in an experiment with 6 birds in which supplements of liver fat and rice in doses equivalent to 12-35 Cals. were administered no increase in weight was observed with this supplement. On the other hand birds on the rice diet supplemented with the vitamin B<sub>1</sub> concentrate and 2 g. protein ingest  $85 \pm 10$  Cals. per day and show

good increases in weight. The daily intake of protein is important. Polished rice [Plimmer, 1921; Rosenheim and Kajiura, 1908] contains 6-7 % protein whilst whole wheat which forms a satisfactory diet for the pigeon contains 11 %. From these figures and the values of the food intakes the daily consumption of 1.2-1.7 g. protein by a bird on polished rice is about 50 % lower than the 3.37 g. consumed by the bird on whole wheat. That the low percentage of protein in polished rice contributes considerably to the failure of birds to regain maximum weight on polished rice supplemented by vitamin B<sub>1</sub> concentrate is borne out by experiments designed to show the effect of including an additional protein supplement in the daily ration. In these experiments we have endeavoured to simulate a diet of whole wheat by raising the protein intake to 3.2-3.6 g. per day by supplements of caseinogen or wheat gluten. In all cases where the protein intake is increased there is a further rise in weight above the level reached with the vitamin concentrate alone. This response, however, does not result in full recovery in all cases but appears to be determined by the intensity of the original depletion of stored vitamins. The effect of a supplement has been studied in 70 birds. In general birds under test were submitted to a depletion period of varying duration, and thereafter each received daily 12 doses of the vitamin concentrate until the weight curve showed a definite plateau. A supplement of 2 g. caseinogen or 2 g. gluten was administered until maximum weight or a constant weight level had been attained. In a few cases the protein supplement was begun simultaneously with the administration of the vitamin concentrate. In the case of 6 birds administration of caseinogen was preceded by a short period during which they received certain amino-acid fractions obtained by hydrolysis of caseinogen. The data are summarised in Table II for caseinogen and gluten respectively. In the experiment with caseinogen it will be seen that for those birds the weight of which did not fall below 70 % of the maximum during the preliminary depletion period full recovery of weight occurred in 70 % of the cases. The time taken for full recovery in these birds varied from 30 to 60 days. On the other hand only 46 % of those birds submitted to a longer depletion subsequently recovered maximum weight with the caseinogen supplement. Among the birds of this group, which failed to make full recovery death occurred in 40 % of the cases. The efficiency of the caseinogen was in no way impaired by autoclaving it at 120° for 2.75 hours. Two birds of the long depletion group received daily 2 g. autoclaved caseinogen. Bird 643 regained maximum weight within the normal period whilst the weight of bird 822 was not further improved by the substitution of unheated caseinogen. The results with gluten were substantially the same as with caseinogen. In the short depletion group no less than 87 % regained maximum weight as compared with 44 % for the birds submitted to long depletion. Four birds of the short depletion group had been previously used in the corresponding test with caseinogen. The weight curves show a close parallelism for the two supplements. The fact that, when the protein intake is increased by administration of caseinogen or gluten, gains in weight are produced, suggests that the inadequacy of the protein intake of birds on polished rice constitutes one factor limiting the full weight recovery under the present experimental conditions. This confirms the conclusion reached from the study of the food intakes on whole wheat and polished rice (Table I).

The failure on the part of some birds, submitted to a long period of initial depletion, to respond fully to the protein supplements is open to several possible interpretations. Prolonged subjection to a deficient diet may lead to irreversible tissue destruction which is not reparable even when a complete diet is substituted. This hypothesis is only tenable if a bird which fails to regain weight on the basal

diet fails also when placed on a whole wheat or mixed corn diet. It is also possible that unpalatability of the basal rice diet may produce a restriction in the food intake with the consequent failure to attain maximum weight. Although some reduction of the caloric intake has been observed in birds on rice as com-

pared with those on whole wheat, it seems unlikely that mere unpalatability of the diet will account for the incomplete weight recovery, since the majority of the short depletion birds are fully restored to maximum weight and in the case of the females, the diet meets the requirements of egg laying. There remains the possibility that prolonged depletion has produced a deficiency of a factor which we here call vitamin B<sub>3</sub>. If this is the case, birds which have failed to regain maximum weight when supplied with vitamin B<sub>1</sub> and protein, should do so when vitamin B<sub>3</sub> is administered.

*The effect of vitamin B<sub>1</sub>, vitamin B<sub>3</sub> and protein.*

Three types of extract have been used in these experiments. Preparation A was obtained as follows: 2 kg. of sheep-liver fresh from the slaughter house were finely minced and treated overnight with 8 l. 97 % alcohol. After filtering the clear yellow solution the liver residue was again twice extracted with alcohol and the combined filtrates concentrated *in vacuo* at 40–50° to a small volume. During this process a considerable amount of lipid material separated out. The extract was now shaken repeatedly with ether until the ether remained colourless, and a white solid separating during this treatment was filtered off. The syrupy yellow fluorescent liquid (preparation A) was administered in amounts equivalent to 5–10 g. of original wet liver. The ethereal solution of fats was freed from ether and taken up on polished rice (preparation B). It was administered in doses of 0.5–1.5 g. The third preparation C was obtained by submitting dry powdered liver, previously extracted with 97 % alcohol, to mild hydrolysis with N/10 HCl for 90 min. The hydrolysate was filtered hot and after neutralisation was given in doses equivalent to 5–10 g. dry powder. It was prepared fresh daily to prevent loss of vitamin B<sub>3</sub> potency [O'Brien, 1934]. Table III summarises data which illustrate the vitamin B<sub>3</sub> activity of these preparations. The birds used in the

<sup>1</sup> Subsequently regained maximum weight without liver supplement.

<sup>2</sup> Died during course of experiment.

NOTE. All birds received basal rice diet and 12 doses vitamin B<sub>1</sub> daily. One bird failed to respond to preparation A or subsequently to wheat.

tests had maintained a stationary weight for 20–60 days before the administration of the preparations.

In a preliminary test birds 722 and 9 were given doses of a crude alcoholic extract of liver. During the course of this test, which was not continued until maximum weight had been established, the high daily average gain in weight of 6–8 g. was observed. Tests performed with the ether-soluble fraction, preparation B, and the aqueous fraction, preparation A, showed clearly that the activity was concentrated in the latter. Thus preparation A gave daily gains in weight of 1–4 g. during the period of testing for 6 birds. Bird 445 which failed to rise in weight was an exception and did not respond subsequently to whole wheat. In 3 birds tested, the experiment was continued until maximum weight had been established. Preparation C also showed considerable activity in spite of preliminary extraction of the fresh liver with alcohol. The observed increments in weight though small are in our experience significant particularly since the growth rate is slow when a bird approaches its maximum weight. It was hoped that a more potent preparation might be obtained from autolysed liver. We have found, however, little or no activity in preparations of this type. The extracts of vitamin B<sub>3</sub> used in these experiments contained amounts of the antineuritic factor which would increase the dose of the vitamin B<sub>1</sub> given daily by 7–14 units. Our experience of the effect of the daily administration of 20–30 doses of vitamin B<sub>1</sub> leads us to conclude that the activity of our liver preparations cannot be explained in terms of their vitamin B<sub>1</sub> content but is due to the presence of vitamin B<sub>3</sub>. It is to be noted that the vitamin B<sub>3</sub> effect of these concentrates fully manifests itself only when the birds' intake of protein is adequate. For in an experiment with 4 birds on polished rice supplemented with vitamin B<sub>1</sub>, doses of liver extract equivalent to 20 g. liver produced rises in weight of 0.5–1.5 g./day which are distinctly lower than the initial daily increments observed in birds of short depletion on polished rice when caseinogen is added.

#### *The storage of vitamin B<sub>3</sub>.*

The evidence presented suggests that significant depletion of vitamin B<sub>3</sub> only becomes manifest when the body weight has fallen below 70 % of the maximum. In most birds this stage is reached within 25–35 days, *i.e.* after a period rather longer than is required to deplete the reserves of the antineuritic vitamin. The depletion on polished rice is not complete since in all cases studied some weight recovery is made when protein is added to the diet. Nevertheless, the rate of depletion of vitamin B<sub>3</sub> may be influenced by the multiple deficiencies of polished rice. Thus, a different picture is obtained if the birds, originally at maximum weight, are placed on a diet complete in all known dietary constituents except vitamin B<sub>3</sub>. Such a condition is approximately attained if the bird at maximum weight is transferred from wheat to our basal diet supplemented with vitamin B<sub>1</sub> and protein. 18 birds have been maintained under these conditions for periods of 52–146 days. In some of these cases the bird had previously risen to maximum weight without addition of the liver supplement; in others this had been given to establish maximum weight. Weight at this level without additional vitamin B<sub>3</sub> is not fully maintained (Table IV). The decline which occurs, however, is very gradual and is of a different order from that seen in birds on polished rice alone. In certain cases a vitamin B<sub>3</sub> preparation was given at the end of the maintenance period. Recovery to maximum weight then occurred (Table V). It would appear that the reserves of vitamin B<sub>3</sub> in the bird are held in some firmly bound state and are only liberated as the result of tissue disintegration such as occurs on a diet involving multiple deficiencies.

Table IV. *The decline in weight of birds on a diet of rice, vitamin B<sub>1</sub> and protein.*

## DISCUSSION.

The experiments described indicate that the daily consumption of rice by a pigeon does not suffice to ensure an intake of protein which is adequate to restore and maintain maximum weight. This conclusion is subject to certain qualifications. In the first place, it has been assumed that the supplements of caseinogen and gluten carry no significant amount of any essential dietary constituent other than protein. The necessity for additional protein is shown by the fact that birds after depletion on polished rice show initial gains in weight of 0.5–1.5 g./day when given liver extract alone as compared with initial gains in weight of 5–10 g. when receiving caseinogen in addition. Secondly, while we believe that our experiments allow us to conclude that limitation of protein rather than total caloric intake is one of the factors which prevent full weight recovery on polished rice, the evidence does not differentiate between limitation of protein *per se* and a deficiency of some specific amino-acid. Experiments bearing on this point are still in progress. Thirdly, the response to an adequately adjusted protein intake is only partial or may be altogether absent if the preliminary period of depletion on polished rice results in a fall of weight below 70 % of the maximum. In such cases recovery is limited by the appearance of a deficiency of vitamin B<sub>3</sub> which is wholly or largely lacking in the diet. This deficiency can be corrected by the administration of vitamin B<sub>3</sub> in the form of extracts of liver. Our experiments, therefore, seem to indicate that two factors at least are necessary to promote weight restoration in pigeons on polished rice supplemented with vitamin B<sub>1</sub>: (a) protein in adequate amount and (b) vitamin B<sub>3</sub>.

## SUMMARY.

1. Pigeons on a polished rice diet supplemented with vitamin B<sub>1</sub> concentrates alone show an early rise in weight which may be followed by a slight decline suggesting deprivation of a stored factor or factors.

2. Comparison of the food intakes of birds on such a diet and on whole wheat shows that although the caloric intake of the bird is satisfactory for its normal maintenance, the amount of protein ingested is inadequate.

3. It is shown that this deficiency of protein in polished rice can be remedied by the addition of caseinogen or gluten to the basal diet whereby a recovery in weight is produced.

4. The extent of this recovery varies with the degree of depletion of a stored vitamin factor, namely vitamin B<sub>3</sub>. 54 % of the birds subjected to long depletion periods fail to regain their original maximum weight when receiving a vitamin B<sub>1</sub> concentrate and protein alone.

5. This failure to rise in weight is remedied by the addition of vitamin B<sub>3</sub> in the form of liver concentrates to such diets.

The authors wish to thank Prof. Peters for his continued encouragement and advice. One of us is indebted to the Medical Research Council for a personal grant.

## IV. THE BLOOD AMMONIA, WITH OBSERVATIONS ON NORMAL HUMAN BLOOD.

By EDWARD JOSEPH CONWAY.

*From the Department of Physiology and Biochemistry, University College,  
Dublin.*

*(Received November 1st, 1935.)*

### 1. INTRODUCTION.

THE determination of the free ammonia of circulating blood has long been regarded as one of outstanding difficulty. The early literature, dating from the researches of Nencki [Nencki *et al.*, 1895; Nencki and Zaleski, 1901] has been reviewed elsewhere [*e.g.* Parnas and Heller, 1924; Parnas and Klisiecki, 1926 *etc.*]. Folin and Denis [1912] were the first to find values under 0.10 mg. ammonia-N per 100 ml. If the special conditions likely to affect a determination be not taken into consideration it is possible to obtain results as high as 2.0 mg./100 ml. and many published results are of the order of 0.3 mg./100 ml. A value of about 30 $\gamma$  (0.03 mg.) per 100 ml. has been considered to represent the free ammonia-N in circulating human blood. It will be shown however that the true value is in fact less than one-tenth of this, or less than one part in thirty millions. There are certain reasons why this fact has hitherto escaped observation, and why when this low value was suggested by Henriques and Gottlieb [1924] and by Fontes and Yovanovitch [1925] on quite insufficient grounds, it was then with good reason believed to be erroneous [Parnas and Klisiecki, 1926]. In the first place the methods used did not permit of the ready accumulation of data within the first few minutes after shedding. It was therefore not noticed that the blood ammonia formation was represented by a steep curve which terminated at about the fifth minute. Also the blood was not received directly into a carbon dioxide atmosphere, and maintained there for subsequent analysis; in this way only is the initial rapid formation abolished and the blood ammonia held at its true value for a certain time after shedding.

Methods hitherto in use for blood ammonia determination are either developments of the original Folin technique [*e.g.* Nash and Benedict, 1921, using special absorbers] or a steam-distillation method elaborated by Parnas and Wagner [1921]. The ammonia from 5 ml. blood—or 2 ml. with the Parnas method—is finally present in about 4 or 5 ml. fluid. It is then determined colorimetrically after adding Nessler's reagent. With regard to the possibilities of nesslerisation Van Slyke and Hiller [1933] state in a recent paper that amounts of ammonia-N corresponding to 0.02 mg. ammonia-N per 100 ml. (obtained from 5 ml. blood) are not "visible at all with Nessler's solution". This represents a dilution of 0.001 mg. ammonia-N in 5 ml. Parnas and Heller [1924], on the other hand, speaking of the same volume of fluid say "man kann bei der Analyse von 2 ccm Blut unterscheiden, ob der Ammoniakgehalt etwa 0.045 oder 0.050 mg. in 100 ccm Blut beträgt". They can in other words distinguish between a dilution of

0.001 mg. and 0.0009 mg. ammonia-N in 5 ml. Comparing these two statements it will be noted that marked differences in the reagent sensitivity were found. This may be attributed to some difference in the composition or manner of preparation of the Nessler's reagent. Van Slyke and Hiller make use now of a reagent attributed to Berthelot by Thomas [1912; 1913] who first utilised it for quantitative determination. The reagent is an alkaline solution of phenol and hypochlorite which on heating with ammonia gives a blue colour. It appears to be more sensitive than the Nessler's solution.

In the method to be described the ammonia is finally present in about 0.7 ml. of standard acid (0.0002 *N* HCl in which is incorporated 20% alcohol and methylene blue and methyl red). In determining this ammonia a titration method is used. A definite change at the end-point is clearly visible to any ordinary observer on the addition of alkali corresponding to 0.00003 mg. ammonia-N. With the method used for the ammonia absorption this will correspond to 0.006 mg. (6 $\gamma$ ) ammonia-N per 100 ml. The alkali used is 0.0005 *N* barium hydroxide. The titration error sets the limit of delicacy for the determination since no appreciable error is introduced by the ammonia absorption itself. Practice with the method enables this error to be still further reduced. The titration is carried out with a special burette [Conway, 1934] which delivers 0.1 ml. with the same accuracy as the standard 2 ml. Bang pipette delivers 1.0 ml. or the standard 50 ml. burette delivers 15 ml., namely with a coefficient of variation of 0.12%.

When titrating 0.0002 *N* acid under the above conditions the standard deviation is directly proportional to the volume at the end-point and may be stated as  $1.42 \times 10^{-6}$  millimols per ml. For 0.7 ml. acid with 0.9 ml. at the end-point this corresponds to 0.018 $\gamma$  ammonia-N. For 5 ml. it would correspond to 0.13 $\gamma$ .

This figure for the standard deviation is readily reproducible with the described conditions. Theoretically a reduction of the error to about one-third of this, but no further, remains as a possibility [Conway, 1934].

In the present method the liberation, absorption and determination of the ammonia are all conducted in the one small glass "unit", the ammonia being absorbed in about 0.7 ml. of standard acid.<sup>1</sup> There is no aeration or distillation. Each "unit" corresponds to the complete apparatus of other experimenters. This "unit" has been already described in a previous communication [Conway and Byrne, 1933]. It is similar to a small Petri dish with thick walls from the floor of which a circular inner wall arises to about half the height of the outer. When covered with a glass lid smeared with a suitable fixative (here a mixture of pure solid and liquid paraffin) the "unit" forms a closed compartment with inner and outer chambers. In the centre is placed for the present determination about 0.7 ml. of standard acid, accurately measured, the outer chamber containing the blood and potassium carbonate. The ammonia passes by simple diffusion into the central chamber. In the ordinary use of the "unit" absorption at room temperature takes 2 hours under such conditions, which is too long a period for blood ammonia determinations as there is a steady formation of ammonia in the presence of the alkali. When we consider however that each "unit" is turned out from the same mould with the same dimensions and surface relations, and further, that since after the first few seconds the fluid surfaces are perfectly still a uniform passage of ammonia may be expected and in fact occurs. An error of less than 5% is introduced by cutting short the full absorption, and for the present determination this is of no consequence. Whatever

<sup>1</sup> "Units" of standard size are now available from Messrs A. Gallenkamp, Finsbury Square, London.

accuracy may be lost here is more than compensated for in comparison with other methods by the entire freedom from contamination during the absorption period. In about 10 min. 50 % of the ammonia is absorbed at room temperature and in 15 min. about 66 %. Either of these times may be selected or any intermediate time. The ammonia formation in the presence of the alkali over this period is very small. The exact correction for this ammonia as well as the factor for calculating the complete absorption may be read from a table or curve (see Table 1).

The determination of blood ammonia by the present method offers in the opinion of the writer little more difficulty than that of an ordinary ammonia determination when the "units" have been adequately cleaned and after the blood has been collected. The manner of collecting the blood is however of the greatest importance. Collected straight from the vessel through a paraffined tube into an atmosphere of alveolar air or of pure carbon dioxide, human venous blood has practically no free ammonia.

The importance of collecting in a carbon dioxide atmosphere was first appreciated from a study of a large number of analyses of human blood collected from a vein directly through a hypodermic needle (without syringe) into a small paraffined Erlenmeyer flask. This would correspond to the ordinary manner of collecting—the blood falling through air.

The concentration of blood ammonia plotted against the time of shedding showed a steep rise in the first few minutes reaching then the level of concentration hitherto accepted as representing the normal concentration in the circulating blood. After 3 min. the change of concentration entered upon the slow and somewhat uniform rise described by other workers [*e.g.* Parnas and Heller, 1924]. If the first curve were extrapolated to zero time it passed directly through the origin. If the second were extrapolated it cut the ordinate at 38 $\gamma$  ammonia-N/100 ml., a figure of about the same order as that given by Parnas as the normal content of ammonia in circulating human blood. From a consideration of the results it was thought that the initial stages of ammonia formation after shedding were most probably linked with the corresponding sudden fall in carbon dioxide tension and content of the blood, a hypothesis which proved to be correct on examination. It is very likely therefore that the first stage of ammonia formation is linked with the breakdown of a carbamino-compound, since the slight change of  $p_{\text{H}}$  can scarcely be held to account for so marked a difference.

## II. PROCEDURE OF THE DETERMINATION.

### *Preparation of the "units".*

The whole success of the determination depends on the careful cleaning of the "units". This procedure however may be quite simply and effectively carried out. The special cleaning of the "units" for blood ammonia determination should begin on "units" cleaned and dried in the ordinary way [Conway and Byrne, 1933] or cleaned and stored in weak acid. A little ether is poured into the centre of a "unit" and then discarded, or if the "unit" is taken from weak acid it is treated with alcohol and ether. The whole "unit" is now filled with approximately 0.005 *N*  $\text{H}_2\text{SO}_4$  and kept 1 hour. The acid is then discarded and the "unit" well rinsed with tap water and subsequently a few times with distilled water, the last drops being shaken out and the "unit" allowed to dry in air, or if not required that day filled with distilled water. With this simple routine excellent results are obtainable from the beginning. Where the "units" have been stored in weak acid further soaking may seem redundant. In practice however the routine outlined

will probably be found the safest, owing to the occasional inadequate soaking of crowded "units". We have found the ordinary laboratory distilled water quite suitable for use. It should however give an approximately neutral tint with methyl red-methylene blue indicator. Pyrex lids are cleaned at the same time and washed with distilled water, being dried in air or with clean filter-paper.

Into the central chamber of each dry "unit" is now run 0.7 ml. of 0.0002 *N* HCl (in which is incorporated methyl red-methylene blue indicator and 20 % alcohol—see below). The acid is delivered from a straight-tube pyrex pipette without blowing, the tube being marked at 0.7 ml. approximately and drawn out at the end. It is standardised for exact delivery without blowing out. Into the outer chamber is delivered in a similar manner 1 ml. of saturated  $K_2CO_3$  from a similar pipette with 1 ml. mark. A pyrex lid smeared with the fixative (a mixture of pure liquid and solid paraffins as described below) is placed in position and the "units" so treated are left for 30 min. Any final traces of ammonia in the carbonate or "unit" will have passed within that time into the central chamber. The ammonia blank value should not exceed 0.1  $\gamma$  ammonia-N.

#### *The collection of the blood.*

The manner of collection will depend on the nature of the investigation. If the real concentration of free ammonium ions in the circulating blood is required the blood must be received into a carbon dioxide atmosphere. For this purpose alveolar air will suffice. In the present determinations a hypodermic needle was inserted into an arm vein. A tube coated with solid paraffin internally was attached to the needle by the minimum quantity of rubber tubing at the joint, the rubber being also coated. The first few drops of blood were discarded and then the collecting tube dipped down to the end of a tonometer of about 300 ml. capacity lined internally with solid paraffin and filled previously with alveolar air, and containing a little ammonia-free potassium or lithium oxalate. After collecting the required amount the tube was at once removed, alveolar air again introduced, the tonometer finally stoppered and the blood mixed. The alveolar air was first passed through two small wash-bottles, the first containing weak acid and the other serving as a trap. It is possible that this procedure was unnecessary, but it ensured freedom of the air in the tonometer from ammonia. Where pure carbon dioxide was employed it was delivered into the tonometer from a cylinder after passing through two similar wash-bottles.

#### *The ammonia determinations.*

When introducing the blood into the "unit" 1 ml. is removed from the flask in a long pyrex pipette similar to those previously used and delivered into a "unit" without blowing. The "unit" for this purpose is slightly tilted by resting on a spare lid, the exact delivery time being noted. The pipette should deliver the blood rapidly. After the introduction of the blood the slightly detached lid is closed at once and the fluids mixed by rotating about 20 to 25 times. After 10–15 min. the lid is removed and the acid titrated with 0.0005 *N*  $Ba(OH)_2$  solution from the burette already described [Conway, 1934]. The strengths of acid and alkali given are suitable for blood concentrations up to 0.2 mg. ammonia-N/100 ml.

*Calculation of the result.* The standardisation of the burette divisions in terms of ammonia titrated may be made from the alkaline or acid side. The 0.0005 *N*  $Ba(OH)_2$  remains quite stable over a long period in the little reservoir bottle of the burette. No deterioration has been observed after a fortnight, provided that

the contents of the delivery tubes are firstly run out before a series of titrations, so that the alkali used in titrating has not long left the reservoir bottle. The barium hydroxide is made up at the beginning from distilled water which gives the same reaction as the desired end-point. Traces of carbonate in the water do not interfere with the titrating alkalinity. The delivery volume of the burette is then given by a constant factor, the ammonia absorbed being calculated with the aid of Table I.

Table I.

Time allowed for absorption min.	Allowance for the extra ammonia produced in the presence of the alkali and absorbed in the time allowed $\gamma$ ammonia-N	Factors for obtaining the full absorption of the blood ammonia
10	0.025	1.95
11	0.029	1.84
12	0.035	1.74
13	0.040	1.66
14	0.046	1.59
15	0.052	1.52
16	0.059	1.46
17	0.065	1.42
18	0.071	1.38
19	0.078	1.34
20	0.084	1.31

The above data are valid for the "unit" of dimensions described in a previous communication [Conway and Byrne, 1933]. They apply to the addition of 1 ml. blood to 1 ml. saturated potassium carbonate at 18°. For other temperatures the absorption factor in the third column is decreased 2%, for each increase of 1°. Where the room temperature differs by more than a few degrees from the standard temperature it is well to keep to the shorter absorption times since the allowance for the ammonia produced in excess in the presence of added alkali is then very small, and changes therein will have only a slight influence.

Example: 1 ml. of blood analysed at room temperature of 18°.

Blank value ... ..	21.7 cm. on scale
Each cm. on burette scale ... ..	0.070 $\gamma$ ammonia-N
Filled unit titrated after 11 min. ... ..	19.6 cm.
Allowance for ammonia produced and absorbed in presence of the alkali over 11 min. (see Table I) ...	0.029 $\gamma$ ammonia-N
Factor for full ammonia absorption corresponding to 11 min. (see Table I) ... ..	1.84

Ammonia-N in 1 ml. blood is therefore

$$\{(21.7 - 19.6) \times 0.070 - 0.029\} \times 1.84 = 0.217 \gamma.$$

Ammonia-N/100 ml. is therefore 21.7  $\gamma$  (0.0217 mg.).

The absorption factors in column 3 of Table I are in experimental and theoretical agreement with the equation

$$\frac{x}{a} = (1 - e^{-0.072t}),$$

where  $x$  is the fraction of the total  $a$  absorbed after the time  $t$ . (The equation has the same form as that for a unimolecular reaction.) For the computation of the figures in column 2 the formation of ammonia in the presence of the alkali has been experimentally determined for human blood as 0.0088  $\gamma$  ammonia-N per min. The amount absorbed from this cause could be simply determined without very appreciable error by regarding half the amount formed during the period

to be present as an initial concentration. It may be more accurately determined from the equation

$$x = K_2 t - \frac{K_2}{K_1} (1 - e^{-K_1 t}),$$

where  $x$  is the amount absorbed in time  $t$ ,  $K_2$  is the constant expressing the rate of formation, namely  $0.0088\gamma$  per min. and  $K_1$  the absorption constant or  $0.072$ . The values calculated will depend as before on the temperature, but for the shorter times this effect can be neglected.

#### *Notes on solutions required.*

*0.0002 N HCl containing reagent.* This is made from stock  $0.01 N$  acid, and stock reagent formed from 50 ml. of  $0.1\%$  methylene blue in alcohol and 200 ml.  $0.1\%$  methyl red in alcohol. The stock reagent is stored in a brown bottle and keeps indefinitely. 2 ml. of the reagent are run into a 200 ml. volumetric flask and 40 ml. of pure alcohol. Distilled water is added to within about 5 ml. of the mark and the mixture brought to the end-point colour (complete absence of reddish tint) by dropping in approx.  $0.01 N$   $\text{Ba}(\text{OH})_2$  from a 1 or 2 ml. pipette. 2 ml. of the stock  $0.01 N$  acid are now added and the mixture brought to the mark with distilled water. The distilled water used should have the reaction of the required end-point or deviate but little from it.

*0.0005 N  $\text{Ba}(\text{OH})_2$ .* This is formed by pipetting 2.5 ml. of  $0.2 N$   $\text{Ba}(\text{OH})_2$  (or 5 ml. of  $0.1 N$ ) into distilled water in a litre flask and making up to the mark. The burette reservoir is filled at once with this solution and will remain for a long period quite unchanged in strength. When the burette reservoir is filled and attached *etc.* the solution may be allowed to settle overnight.

*Saturated  $\text{K}_2\text{CO}_3$ .* A large stock of saturated carbonate is made up in the ordinary way. About 200 ml. are decanted into a pyrex Erlenmeyer flask with glass stopper and some beads added. This alkali is boiled vigorously for about 20 min. If much water is lost it may be made good by addition. On cooling some solid crystals of carbonate should be in evidence.

*Oxalate (ammonia-free).* About 50 ml. of a strong solution of potassium oxalate are evaporated in an open pyrex dish after bringing to  $p_{\text{H}}$  10 or 11 by adding a little alkali, the reaction being tested by a universal indicator. The water volume is maintained by occasional addition. The mixture is kept boiling for about 10 min. and then evaporated until the solid separates; after cooling the crystals are filtered off on a small Büchner funnel and preserved in a desiccator.

*The fixative.* The same fixative is used as described for chloride determinations [Conway, 1935]. 40–50 g. paraffin, M.P.  $49^\circ$ , are melted with 80 ml. of pure liquid paraffin and cooled. Vaseline should not be used as it contains traces of ammonia.

*Stock ammonia standard.*  $0.471$  g. of pure  $(\text{NH}_4)_2\text{SO}_4$  is dissolved and made up to a litre with distilled water.  $0.1$  or  $0.2$  ml. *etc.* of this diluted to 100 ml. correspond to 10, 20  $\gamma$  *etc.* of ammonia-N/100 ml.

*Ammonia-free water.* This may be made up in the usual manner by distilling dilute sulphuric acid and discarding the middle portion of the distillate. The distilled water of the laboratory was in fact found to be almost perfectly free from ammonia.

### III. EXPERIMENTAL.

#### *Blank values.*

A series of 24 blank determinations was carried out with the above technique, and standard solutions. The mean of the series (Table II) gave 21.4 cm. reading on the burette scale, corresponding to  $0.214$  ml., the tube being calibrated to  $0.001$  ml. divisions. Direct titration of the acid gave a mean value of 22.3 cm.

Table II.

Burette reading cm.	Deviation from the mean value cm. on scale	Deviation from the mean value as $\gamma$ ammonia-N
21.8	+0.4	+0.028
21.4	0.0	0.000
21.6	+0.2	+0.014
21.5	+0.1	+0.007
21.3	-0.1	-0.007
20.6	-0.8	-0.056
21.8	+0.4	+0.028

The table gives the first seven of a series of 24 blanks. Omitting one aberrant value the standard deviation is 0.30 cm. or 0.021 $\gamma$  ammonia-N, a figure practically the same as that resulting from immediate titration of a succession of acid deliveries when expressed in the same manner.

The standard deviation of the individual blank titration, omitting two aberrant results, was 0.30 cm., corresponding to 0.021 $\gamma$  ammonia-N. The standard deviation for the titration procedure carried out directly with a succession of deliveries in the one unit is 0.018 $\gamma$  N. The blank values therefore show no significant difference from the titration itself with regard to variability, and are in this sense therefore practically perfect. Table II gives the first seven blank titrations of the series. Omitting the two aberrant results 20 of the remaining 22 blank values did not exceed 0.4 cm. deviation from the mean, corresponding to 0.028 $\gamma$  N, and the greatest deviation was 0.8 cm. or 0.056 $\gamma$  ammonia-N.

#### *Determinations of standard solutions.*

From the stock  $(\text{NH}_4)_2\text{SO}_4$  described above a number of standards were made up as required containing 10, 20 and 100 $\gamma$  ammonia-N/100 ml. respectively (0.1, 0.2 ml. of the stock made up to 100 ml.). Table III gives a summary of the

Table III. *Standard solutions.*

Strength of standard used $\gamma$ ammonia-N/100 ml.	No. of determinations	Standard deviation of the individual determination $\gamma$ ammonia-N/100 ml.	Maximum deviation of a single determina- tion from theoretical $\gamma$ ammonia-N/100 ml.
10.0	11	3.5	7.5
20.0	8	4.7	8.1
100.0	5	5.9	8.8

Table IV. *Determinations of the standard 10 $\gamma$  ammonia-N/100 ml.,  
absorption being terminated after 10-15 min.*

Burette reading subtracted from blank value cm.	Time of absorption min.	Ammonia absorbed $\gamma$ ammonia-N	Theoretical value for the absorption time $\gamma$ ammonia-N	Difference from theoretical $\gamma$ ammonia-N	Ammonia-N found in standard $\gamma$ ammonia- N/100 ml.
1.1	10	0.077	0.051	-0.026	15
0.7	11.5	0.049	0.056	+0.007	9
1.0	12.5	0.070	0.059	-0.011	12
0.8	13	0.056	0.060	+0.004	9
0.7	14	0.049	0.063	+0.014	8

The blank value for the above table was determined as the average of five results. The table gives the first five of a series of eleven determinations of the standard 10 $\gamma$  ammonia-N/100 ml. using the method of suspended absorption. The standard deviation of a single ammonia absorption in the unit from the theoretical is 0.017 $\gamma$  ammonia-N. This may be compared with 0.018 $\gamma$  for the titration procedure itself and 0.021 for the blank values. The standard deviation of the individual determination of the ammonia content in the standard is 3.5 $\gamma$  ammonia-N/100 ml.

results obtained, from which it will appear that the accuracy of the determinations is only limited by the titration error, the ammonia absorption itself giving rise to no appreciable error. Thus, for the 10 determinations of 1 ml. of the 10 $\gamma$ /100 ml. standard given in Table IV, 9 of the 10 did not deviate from the theoretical quantity of ammonia expected by more than 0.026 $\gamma$  which is a result nearly identical in value for the blank determinations or in turn for that of the pure titration error. The standard deviation of the ammonia divergence from the theoretical for these lowest determinations is in fact 0.017 $\gamma$  ammonia-N, which compares with 0.018 for the pure titration and 0.02 for the blanks. The difference between these values is merely an expression of sampling error.

*The absorption rate of ammonia from blood-carbonate mixture.*

It was expected before investigating this rate that some divergence would be found from that of standard solution-carbonate mixture. Such divergence however would be of a constant nature and expressible by a factor or incorporated in the factors of Table I. Two experiments carried out to determine the point gave results however showing no appreciable divergence (Table V). In these experiments 0.2 ml. of standard  $(\text{NH}_4)_2\text{SO}_4$  containing 2.24 $\gamma$  or 1.12 $\gamma$  ammonia-N was introduced into the empty outer chamber of a "unit", the central chamber containing the acid as before, 1 ml. of freshly shed blood (10 min. after shedding into an open vessel) was introduced, the lid placed in position and 1 ml. of saturated carbonate then run in *etc.* The absorption was terminated after 10 min. and the acid titrated. A similar experiment was set up, water being substituted for blood; also corresponding blank experiments using 0.2 ml. water instead of the standard  $(\text{NH}_4)_2\text{SO}_4$ . From Table V it will appear

Table V. *Absorption rate of ammonia from carbonate-blood mixtures.*

Contents of outer chamber before adding 1 ml. saturated $\text{K}_2\text{CO}_3$	Ammonia added $\gamma$ N	cm. on burette subtracted from blank	Rate of ammonia absorption per $\gamma$ $\text{NH}_3$ -N added cm. per 10 min.
1 ml. blood <i>plus</i> 0.2 ml. standard ammonia solution (0.0008 N)	2.24	13.3	5.9
1 ml. blood <i>plus</i> 0.2 ml. standard ammonia solution (0.0004 N)	1.12	6.4	5.7
1 ml. water <i>plus</i> 0.2 ml. standard ammonia solution (0.0004 N)	1.12	6.6	5.9
Corresponding blank values.			
1 ml. blood <i>plus</i> 0.2 ml. water	0.00	18.2	—
1.2 ml. water	0.00	21.8	—

The absorption for the above experiments was terminated after 10 min. Duplicate determinations were carried out in each case. In the experiments above the carbonate was added at once after the mixing of blood and standard ammonia solution.

that the percentage of the added ammonia absorbed after 10 min. is the same with blood as with water, within the error of the determination. In these experiments the added ammonia was only in momentary contact with the blood before addition of the alkali. It is to be noted that the total outside fluid before the carbonate addition was 1.2 ml. so that the absorption rate is slower than where only 1 ml. is present [see Conway and Byrne, 1933].

*The effect of saturated potassium carbonate on the ammonia formation in shed blood.*

In determining this effect 25 ml. of recently shed blood from each of two subjects were mixed with 25 ml. of saturated  $K_2CO_3$  in a 50 ml. Erlenmeyer flask provided with a paraffined rubber stopper. The flasks held in fact somewhat more than 50 ml. so that mixing could be adequately performed on inserting the stopper. When a sample of blood was required 2 ml. of the mixture were taken and run into the outer chamber of a prepared "unit" containing 0.7 ml. of the standard acid in the central chamber. The sample was quickly taken from the flask after inserting the pipette down to the bottom of the flask and the cork replaced at once. The ammonia vapour diffusing into the small air space left and in equilibrium with the mixture was considered negligible, and the removal of the sample from the bottom of the flask would in any case ensure against loss of ammonia. The samples in the "unit" were allowed 14 min. for absorption. In each case samples were taken after 4 to 8 min. and then after about 1 hour as

Table VI. *The effect of saturated potassium carbonate on blood ammonia formation.*

	Time after mixing equal vols. blood and carbonate min.	Time of absorption in "unit" min.	cm. on burette, corresponding to the absorption	Ammonia-N absorbed $\gamma$ N
Blood I	4.5	14	3.2	0.22
	6.4	"	3.9	0.27
	7.7	"	3.6	0.25
Blood II	6.7	"	3.8	0.27
	7.8	"	3.7	0.26
Blood I	57.5	"	8.4	0.59
	58.0	"	7.8	0.54
Blood II	52.5	"	7.1	0.50
	53.0	"	6.6	0.46

Ammonia absorbed in "unit" after short period in Erlenmeyer flask, 0.25  $\gamma$  (6.4 min. mean time in Erlenmeyer flask).

Ammonia absorbed in "unit" after long period in Erlenmeyer flask, 0.52 (55.2 min. mean time in Erlenmeyer flask).

Therefore  $(0.52 - 0.25) \times 1.50 = 0.43$  ammonia-N represents the amount formed in 48.8 min. action of carbonate on blood. (The factor 1.50 arises from the suspension of absorption after 14 min. See Table I.) The ammonia formation per min. in the presence of carbonate is therefore 0.0088  $\gamma$  ammonia-N at room temperature.

shown in Table VI. From the mean of the short and long time periods the ammonia formation in the presence of the carbonate appears as 0.0055  $\gamma$  ammonia-N per min. with the 14 min. period of absorption or 0.0088  $\gamma$  ammonia-N altogether, the ammonia formation during the absorption period being the same in both the short and long periods disappears in the subtraction.

*The percentage error involved in the suspension of the ammonia absorption.*

From the foregoing paragraphs of this section it is clear that as the ammonia for determination approaches minimum quantities, the only error involved in the determination is that of the titration itself. In a simple and easy manner therefore all extraneous contamination with acid or alkali or ammonia from other sources is removed. At the same time the question arises of the degree of error involved in the 10-15 min. restriction of absorption for a given quantity of ammonia. This had been previously examined in a number of early experiments

with the "unit". Sixteen determinations of 1.0 ml.  $(\text{NH}_4)_2\text{SO}_4$  solution containing 46.4  $\gamma$  ammonia-N were carried out, the ammonia being absorbed in 1 ml. of 0.00333 *N* HCl in the central chamber and subsequently titrated with 0.001333 *N* Ba(OH)<sub>2</sub> from a Bang burette. The absorption was terminated in each case after 10 min. The mean absorption at 17° was 49% of the added ammonia. The coefficient of variation of the individual determination from the mean value was 2.8%. All the sixteen determinations were under 5% deviation from the mean, the two highest deviations being 4.9%.

#### IV. RESULTS.

##### *The ammonia content of normal human blood.*

(a) *The blood ammonia value determined after collecting in an open vessel.* Here the blood was collected from an arm vein through a hypodermic needle. The blood was allowed to fall in a stream into a small Erlenmeyer flask lined with solid paraffin, containing a little ammonia-free oxalate, the exact time of shedding being noted with a stop-watch. About 25 ml. were collected as a rule. After shedding and quickly mixing with the oxalate, 1 ml. volumes were pipetted successively into a number of prepared units, the exact times of mixing with the carbonate being noted. In this way a large number of determinations could be grouped around the first few min. after shedding. The determinations were made on 7 subjects, 12 separate samples of about 25 ml. blood being taken. Up to 2.75 min. after shedding there are 29 separate determinations of the blood ammonia, and after this period 43 determinations. The results are summarised in Table VII, and in Figs. 1 and 3. In Fig. 1 the two stages of the blood ammonia

Mean room temperature = 16°.

formation are clearly shown. The first rise extrapolated over 0.75 min. passes through the origin. The same result may be observed from the table where the rates of the ammonia formation are given. If the rate during the first 0.75 min. is as fast as that in the next min. the original ammonia must be either zero or practically indistinguishable therefrom. Fig. 2 shows the course of the formation for a single subject (F.K.), a rapid succession of analyses being carried out immediately on shedding. Eight determinations were made for times up to 4 min. after shedding. The means of each two analyses in order of time are given in the graph. The same characteristics are observed as in the general graph.

In general after the first rapid rise the rate of formation of blood ammonia within the succeeding few hours is 0.37  $\gamma$  ammonia-N per min. per 100 ml. around a temperature of 16°. Fig. 3 shows the effect of incubating the blood after shedding (upper curve) at 22.5°. This upper curve was constructed from determinations on two subjects. The rate at 22.5° after the first few min. is 0.82  $\gamma$  ammonia-N per min. per 100 ml.

Fig. 1.

Fig. 2.

Fig. 3.

Fig. 4.

Fig. 1. The curve is constructed from the means of a number of determinations on 12 blood samples (about 25 ml. each) from seven different subjects. The blood was collected in each case direct from an arm vein through a hypodermic needle into an open Erlenmeyer flask lined with solid paraffin. Mean temperature of room, 16°.

Fig. 2. The figure shows the blood ammonia formation after shedding into an open vessel for a single subject (F. K.). Each circle is the mean of a duplicate.

Fig. 3. Curve B is the same as in Fig. 1 on a ten times smaller time scale. Curve A represents the ammonia formation in blood from two subjects maintained at 22°.

Fig. 4. Curve A represents the blood ammonia formation for two subjects, E. C. and F. K., the blood being collected in an open Erlenmeyer flask. Curve B gives the formation of ammonia in blood from the same two subjects collected in alveolar air. Curve C represents the blood ammonia formation after collection in pure carbon dioxide at atmospheric pressure (for the single subject E. C.). This last curve represents the mean line through 11 determinations made up to 128 min.

(b) *The blood ammonia determined after collecting in alveolar air.* The peculiar nature of the true curve of formation after shedding in an open vessel suggested a connection with some factor altering with like rapidity within the first few min. Such a factor would be the carbon dioxide tension and content of the blood. For this reason it was thought desirable to collect the blood directly

from an arm vein into a tonometer filled with alveolar air. To the hypodermic needle was attached a pyrex tube lined with paraffin, the connection being made with the minimum quantity of paraffined rubber tubing. The tonometer, about 250 ml. in capacity, was also lined internally with solid paraffin. It contained some ammonia-free oxalate and was filled with alveolar air which had passed through a small wash-bottle containing dilute acid and another acting as a trap. The taps and stopper of the tonometer were lubricated with liquid paraffin. After insertion of the needle the first few drops of blood were discarded and the collecting tube plunged at once to the bottom of the tonometer. After collecting about 15 ml. blood, the tube was withdrawn, the blood mixed and more alveolar air passed through, the tonometer being then stoppered. Samples of blood for analysis were taken in quick succession, by means of a long-tube pyrex pipette with a mark at 1 ml., the stopper being opened and closed immediately after each sample, alveolar air being occasionally sent through. The blood donors were two subjects whose blood has been previously well investigated by the open method (E.C. and F.K.—Table VII). The blood was taken and analysed under exactly similar conditions and at the same time of day (about 4 p.m.). The surprising result was obtained that for the first 12 min. after shedding the mean value of 11 determinations (6 from one and 5 from another subject) was almost indistinguishable from zero. The initial rise had entirely disappeared. For the first 12 min. practically no distinction could be made between the results returned. The average of 11 such results gave  $3.1 \pm 2.2\gamma$  ammonia-N/100 ml. ( $\pm 2.2$  gives the standard deviation of the mean) with a standard deviation of the individual result of  $7\gamma$  N/100 ml., the highest deviation obtained being  $11\gamma$ /100 ml.

When the ammonia formation is followed beyond 12 min. however it appears that a slow increase is occurring from the period of shedding corresponding to the secondary rise in blood collected in an open vessel. This is shown in Table VIII

Table VIII.

Time after shedding min.	Collected in alveolar air			Collected in open vessel		
	No. of determinations	Mean time min.	Mean conc. $\gamma$ ammonia-N/100 ml.	No. of determinations	Mean time min. after shedding	Mean conc. $\gamma$ ammonia-N/100 ml.

>100	4	148	62	—	—	—

Comparison of the 4th and 7th columns shows the marked difference resulting from collecting in alveolar air as compared with collecting in an open vessel. The figures after the commas—for collection in an open vessel—refer to data assembled 2 years before the preceding values. These latter were taken a day or two before the determinations with alveolar air. Roughly equal numbers of determinations were made for each time period on the blood of each subject. The figures found being very similar for each donor are incorporated together for economy of presentation.

and in Fig. 4. The table summarises the data obtained from two subjects (E. C. and F. K.) the blood from whom had been previously well investigated for open vessel collection. Fig. 4 (upper two curves for the same two subjects) shows a linear ascent of concentration for collection in alveolar air (middle curve, the upper curve being for open collection) up to 40 min., the line of formation pointing directly into the origin.

*The blood ammonia determined after collecting in carbon dioxide at full atmospheric pressure.*

The effect of collecting the blood in an atmosphere of pure carbon dioxide at atmospheric pressure was also investigated, the blood being collected in the same manner as for alveolar air. In this case the tonometer was filled with pure carbon dioxide derived from a cylinder and passed through two wash-bottles as before. The blood donor here was one of the subjects (E. C.) investigated for open vessel collection and for the alveolar effect described in the last section. Table IX gives

100-200	—	53 (2)	7 (1)

The numbers in brackets refer to the number of determinations made.

a summary of the results obtained, the different results of the three methods of collection being compared for one subject. Even up to 128 min. after collection in carbon dioxide the blood ammonia concentration is but little different from zero. The mean value of the 10 determinations made on blood up to this period is  $4.4 \pm 1.3 \gamma$  ammonia-N/100 ml. The mean of the last three observations made at an average time of 68 min. was  $4.3 \gamma$  ammonia-N/100 ml. The mean of the first three at 1.8 min. was  $6.0 \gamma$  ammonia-N/100 ml., no increase occurring therefore over 66 min. After 128 min. one observation gave  $7.0 \gamma$  ammonia-N/100 ml. For a long period after shedding therefore pure carbon dioxide at atmospheric pressure completely prevents all formation of ammonia in human blood and the mean value obtained is only one part in 23 millions. The data for collection in pure carbon dioxide are summarised in Table IX and Fig. 4 (lowest curve).

*Effect of pure carbon dioxide at atmospheric pressure on blood ammonia already formed.*

In experiments carried out to determine this effect, blood collected in a paraffined Erlenmeyer flask was allowed to develop ammonia over 2-3 hours. The ammonia was then determined and at the same time some of the blood was introduced into a tonometer filled with carbon dioxide at atmospheric pressure. The blood was rotated and mixed in the tonometer, the carbon dioxide having been renewed a few times. After 10-15 min. of action the blood was again analysed for free ammonia. The results are shown in Table X. The duplicate

Table X.

Blood	Time after shedding into open vessel	Ammonia-N/100 ml.	Ammonia-N/100 ml. after carbon dioxide (760 mm.) action
	min.	$\gamma$	$\gamma$
I	176	99	101
II	121	107	100

determinations on blood from two different subjects gave 99 $\gamma$  and 107 $\gamma$  ammonia-N/100 ml. before, and 101 $\gamma$  and 100 $\gamma$  ammonia-N/100 ml. after the

carbon dioxide action. It appears therefore that carbon dioxide of this tension although preventing any formation of ammonia over a long period is without effect in reversing the formation once the free ammonium ion has appeared in solution.

## V. DISCUSSION.

### *Accuracy of method.*

With the "unit" described and utilised in previous communications it is shown to be possible to determine ammonia in 1 ml. of standard solutions to an ultimate standard deviation of  $2\gamma$  ammonia-N/100 ml. For the blood ammonia determination as described above, the absorption was limited to 50–70 % of the total (10–15 min.). This limitation with standard solutions comes to mean a determination of ammonia-N to an ultimate standard deviation of  $4\gamma$ . These are exact statements of accuracy and are readily reproducible. How they apply in the actual practice of blood determination will appear from an analysis of the 21 determinations made on blood shed into a carbon dioxide atmosphere within the first 12 min. after shedding. The standard deviation of the individual value in these 21 determinations was  $5\gamma$  ammonia-N/100 ml. (mean value  $3.7$ ). These values include however the 11 values in alveolar air which, from the curve over a long subsequent period, we may suppose to have risen slightly. For the 10 values in pure carbon dioxide the standard deviation found was  $4\gamma$  ammonia-N. For 29 determinations in all carried out on 7 subjects for open collection within the 3rd to the 10th min. afterwards the standard deviation of the individual determination was 6.6 (mean value  $38\gamma$ ). The latter result is in itself remarkable not only for establishing the accuracy of the determinations but also indicating a constancy of ammonia formation under such conditions, since the standard deviation carried out on the same standard solution would in fact be  $4\gamma$  ammonia-N, and a slight rise is also occurring over the 3rd to the 10th min. in blood collected with the open method. For determinations of the blood ammonia described by other workers there are no such precise statements of accuracy. We may select for comparison however the four results published by Van Slyke and Hiller [1933] on the same blood sample. They used 5 ml. blood with each determination in accordance with the Nash and Benedict technique. The mean value was  $48\gamma$  ammonia-N/100 ml. and one of the four determinations deviated by  $7\gamma$ /100 ml. This may be compared with the results of 11 determinations on blood samples from two different subjects, analysed between 3 and 12 min. after shedding. The maximum deviation found was  $5\gamma$  ammonia-N/100 ml. from a mean value of  $38\gamma$  ammonia-N/100 ml. A more exact comparison of the accuracy found by Van Slyke and Hiller, so far as may be judged from their published data, can be made in the following way. In their published figures there are 6 duplicates given and 4 determinations on the same blood, which latter may be regarded as 2 duplicates, and in all therefore, 8. For such minimum quantities the absolute rather than the percentage error is significant and from the following formula we may determine the standard deviation of the single determination

$$2\sigma^2 = \frac{1}{N} \sum (X_1 - X_2)^2,$$

where  $X_1$  and  $X_2$  are the members of a duplicate and  $\sigma$  is the standard deviation required. From the data in question and considering that 5 ml. were used the result is  $0.19\gamma$  ammonia-N. From the results of the present method we have  $0.04\gamma$  ammonia-N (or  $4\gamma$  N)/100 ml. which shows therefore five times the accuracy in absolute quantities and permits the same relative accuracy with one-fifth the quantity of blood.

As mentioned above, Van Slyke and Hiller had the advantage over other workers with this method of a more delicate reagent than Nessler's.

The present method permits of the rapid and easy accumulation of large numbers of determinations. For example, with one blood sample from the beginning of the period of shedding up to the 4th min. 8 determinations were set up and completed within 26 min. In all 159 determinations were assembled, 96 in a later group, in 6 working days.

*The true content of ammonia in human venous blood.*

The examination of the general time concentration curve where the blood was collected in an open vessel (paraffined Erlenmeyer) shows the erroneous conclusions hitherto arrived at from an extrapolation of the secondary rise over the first few min. The true curve of formation rises steeply and apparently from the origin to a concentration level of  $38\gamma$  ammonia-N/100 ml. which is reached about the 3rd min. It enters then on the slow ascent described by other workers.

An entirely different picture is presented if the blood is collected in an atmosphere of alveolar air. The initial steep rise disappears and for the first 12 min. after shedding the mean value of 11 determinations is  $3.1 \pm 2.2\gamma$  ammonia-N/100 ml.

*Is the value in fact zero?* It may be noted that even  $3.1\gamma$  ammonia-N/100 ml. represents one part in 32 millions, and is one-tenth of the very minute value previously thought to represent the true ammonia content of circulating blood. The latter may in fact be zero particularly in the light of the following considerations. Examining the ammonia content after collecting in alveolar air, what seemed when the first 12 min. only were taken into consideration to be a complete cessation of ammonia formation showed itself to be similar to the general slow and secondary rise with the open vessel collection when much longer time periods were investigated (see Fig. 4). The curve of this formation which appears as a straight line up to about the first hour points unmistakably into the origin. The rate of formation as indicated by this line is  $0.66\gamma$  ammonia-N/100 ml. per min. If we consider that the mean time for the 11 determinations over the 12 min. period is 5.6 min., then in this period we may expect  $3.7\gamma$  ammonia-N/100 ml. formed. The mean of the 11 determinations is however  $3.1\gamma$  ammonia-N/100 ml. We can therefore conclude that the ammonia content of circulating human blood is zero from these findings or so small that it is quite beyond any present method of determination. Both the initial steep rise to  $38\gamma$  ammonia-N/100 ml. and the secondary slow rise are stopped by pure carbon dioxide. For a long period (at least 2 hours) after collection in pure carbon dioxide only minimum quantities of ammonia are present. The average up to 128 min. of 10 observations is  $4.4\gamma$  ammonia-N/100 ml.

There now arises for consideration the following question: Is the absence of free ammonia from circulating blood merely an analytical result due to the combination of the free ammonia liberated after adding alkali with free carbon dioxide? Such a point was already raised by Rehberg [1926]. It is conceivable that the ammonia could in this way combine with free carbon dioxide (which presumably would have insufficient time to disappear as carbonate ion) and form ammonium carbamate. This in turn would be slow to disintegrate at the high  $p_H$ . The following facts however completely decide the point. Small quantities of ammonia immediately added to blood should not be recoverable at all or only in very reduced amounts. In fact they are recovered practically quantitatively. Again if the free carbon dioxide operates in such a fashion an increase of twenty times its value should have an extremely marked effect. It has been shown

however that once the ammonia is formed in the blood after shedding, subsequent treatment with pure carbon dioxide at atmospheric pressure has no appreciable effect on its concentration. This completely rules out the above conception of an instantaneous carbamate formation with subsequent slow disintegration.

*The mother substances of the ammonia formed after shedding.*

From the period of the discovery of Embden *et al.* [1928] of the free ammonia in muscle arising from adenylic acid a similar origin for the ammonia formation in shed blood was a recognised possibility. Adenylic acid in blood was quantitatively determined by Buell and Perkins [1928] and a parallel formation of free purine bases and ammonia in blood was demonstrated by Mozolowski [1929] who showed the process of formation to pass through inosinic acid which subsequently broke down to form free purines. The purine-nitrogen formed however only accounted for a fraction of the total ammonia-N. That at least two substances were involved was further demonstrated by Heller and Klisiecki [1935]. Adenylic acid corresponds to their substance B. With intact corpuscles adenylic acid in fact does not break down at room temperature for 24 hours or more. Even at 37° the beginning of this process is only demonstrable after 24 hours. The ammonia formation considered above would therefore, from these findings, have nothing to do with adenylic acid breakdown. The formation would correspond to the substance A of Heller and Klisiecki, which gives rise to upwards of 500  $\gamma$  ammonia-N/100 ml. From the experiments described in this communication it seems very likely that at least the first stage of the formation is due to the breakdown of a carbamate or carbamino-compound. The existence of carbamino-compounds in blood is very probable from the work of Henriques [1928] and in particular that of Meldrum and Roughton [1933]. (This work has been reviewed by Roughton [1935].) Whether however the secondary slow formation of ammonia in shed human blood (using an open vessel) is also associated with a similar breakdown is more doubtful, since although atmospheric tension of carbon dioxide completely excludes it over a long period the  $p_H$  change produced by this tension enters also as a possible factor. The action of carbon dioxide on the ammonia formation 5 min. after shedding was in fact also examined by Parnas and Heller [1924] who used it however with the object of producing hydrogen ion changes and explained the effects produced by reference to this factor. Such results may now be explained very differently, namely by a specific action of carbon dioxide. From the results of Parnas and Heller [1924] at tensions of carbon dioxide ranging from 155 mm. to 0.2 mm. the rate of formation within the first 5 hours or so varied according to the tension from 2 to 5  $\gamma$  ammonia-N/100 ml. per min. (at 20°). At the same time the reaction altered from  $p_H$  6.7 to 8.4. When the reaction becomes markedly alkaline the rate of breakdown of a carbamino-compound becomes considerably reduced, so that in fact with changes of carbon dioxide tension we should have an interplay of two effects on the rate of breakdown. For the second slow rise it will probably be an easy matter to dissociate the  $p_H$  effect and the specific effect of carbon dioxide, though the introduction of new reagents such as phosphate buffers is not altogether free from objection. It is interesting in this connection that Krebs and Henseleit [1932] have also noticed and commented upon a specific carbon dioxide effect in the formation of urea in liver. The rate of formation is markedly reduced when the carbon dioxide content falls, even though the reaction be maintained by the use of phosphate and a sufficiency of carbon dioxide be present for urea production.

Considering that the breakdown of a carbamino-compound is required to explain the first rapid change with open shedding, the question arises is carbamic

acid itself responsible? The instability of carbamic acid and its general association with the ammonium ion in solution would on a first consideration render it very unlikely to account for the change. It is necessary to inquire however if any fraction may be assigned to its breakdown. From the following two equations

we may derive

$$\frac{[\text{NH}_4^+]}{[\text{NH}_2\text{COO}^-]} = \frac{K_G \times [\text{H}^+]}{K_{\text{NH}_3} \times [\text{HCO}_3^-]}$$

Here  $K_G$  has been determined by Faurholt [1922, 1, 2] as 0.33 (being very little affected by temperature) and inserting approximate values for the other components on the right side of the equation we have

$$\frac{[\text{NH}_4^+]}{[\text{NH}_2\text{COO}^-]} = 10^{3.1}.$$

The ammonium ion concentration must therefore be a thousand times greater than that of the anion of carbamic acid. But this latter is about half or a very appreciable factor of the whole carbamic acid present if we accept the dissociation constant given by Faurholt. This constant was very roughly determined as  $10^{-7}$ – $10^{-8}$ . It was in fact placed considerably lower by Wegscheider [1922], namely at  $5.5 \times 10^{-10}$ , a figure which would necessitate the salts of carbamic acid being considerably dissociated. Such dissociation was not found by Faurholt. Considering that no measurable ammonia is present in the circulating blood it is clear that no appreciable amount of carbamic acid can exist therein. The substance in question accepting it as a carbamino-compound must therefore be a derivative of carbamic acid. Such a compound even at the carbon dioxide tension of alveolar air would be practically undissociated into the free amine. Also when the amine is formed a further process of deamination is necessary to explain the appearance of the free ammonia. Further experiments are clearly necessary to warrant any further speculation on such lines.

In conclusion it may be pointed out that apart from the nature of the precursor present, the results described above for the normal human subject remove any real significance from previous determinations of the blood ammonia which purport to represent the actual conditions in circulating blood.

## VI. SUMMARY.

1. A method is described for the determination of very minute quantities of ammonia (less than  $1\gamma$ ) in which the ammonia absorbed is determined to an ultimate standard deviation of  $0.02\gamma$  ( $0.00002$  mg.) ammonia-N. It consists of some additional refinements introduced into the method described in a previous communication [Conway and Byrne, 1933]. Applying the method to the determination of ammonia in 1 ml. blood, the absorption period being limited to 10–15 min., the standard deviation for the determination of minimum quantities of ammonia is  $0.04\gamma$  ammonia-N. In the 10–15 min. period, 50 to 66% of the whole ammonia present is absorbed. The relative error involved in this limitation of the absorption period with the special "units" may be expressed as a coefficient of variation of 2.8%.

2. It is shown that the free ammonia present in shed human blood depends very largely on the manner in which the blood has been collected. When received into a small Erlenmeyer flask directly from a vein a steep rise occurs which

terminates about the 3rd minute, and passes into the slow ascent previously described by other workers. When the first curve is extrapolated over the first 0.75 min. after shedding it passes through the origin. When the second curve is extrapolated it cuts the ordinate at  $38\gamma$  ammonia-N/100 ml. corresponding to the concentration previously accepted as representing the concentration of free ammonia in circulating blood.

3. When the blood is received into an atmosphere of alveolar air for about the first 12 min. after shedding the quantity found is scarcely distinguishable from zero, being  $3.1\gamma$ /100 ml. It is quite indistinguishable at zero time when allowance is made for the slight ammonia formation in the period as calculated from the subsequent rise over 2 hours. The first steep rise is completely absent, the secondary slow ascent being still present. This curve of formation is a straight line up to about 1 hour and points directly into the origin.

4. Blood received into pure carbon dioxide at atmospheric pressure forms no ammonia over a long period after shedding. The average of 11 observations up to 128 min. after shedding is  $4.4 \pm 1.3\gamma$  ammonia-N/100 ml.

5. When ammonia is once formed after shedding subsequent action of carbon dioxide even at full atmospheric pressure has no noticeable effect in diminishing the concentration present.

6. It is concluded from the controlling influence of the carbon dioxide tension on ammonia formation that the first stage of ammonia formation in shed blood is associated with the breakdown of a carbamino-compound.

7. The action of saturated potassium carbonate on blood when mixed in equal quantities has also been investigated. It is shown that  $0.0088\gamma$  ammonia-N per min. per ml. blood is formed in the presence of the alkali.

The results summarised here are based on a large number of determinations (159 in all) on human blood.

# CCCXXX. STUDIES IN FAT METABOLISM.

## IV. ACETOACETIC ACID BREAKDOWN IN THE KIDNEY.

By JUDA HIRSCH QUASTEL

AND ARNOLD HERBERT MAURICE WHEATLEY.

*From the Biochemical Laboratory, Cardiff City Mental Hospital.*

*(Received November 1st, 1935.)*

THE following paper is concerned with the breakdown of acetoacetic acid in the kidney. A preliminary study of this phenomenon has already been made [Jowett and Quastel, 1935, 3] and the experimental methods used have already been described in detail [Parts I, II, III, Jowett and Quastel, 1935, 1, 2, 3]. Both the Barcroft and Warburg apparatus have been used.

Acetoacetic acid has been determined manometrically as usual (see Part I), kidney cortex slices being removed from the medium at the end of a period of 2 hours at 37°. The initial concentration of sodium acetoacetate (prepared by the method of Ljunggren [1924], alcohol being removed by vigorous aeration at reduced pressure) was determined in each experiment, a control vessel containing acetoacetate without tissue being kept in the bath at 37° for the duration of the experiment.

### *Aerobic breakdown of acetoacetic acid in the kidney.*

It was demonstrated in the preceding paper (Part III) that the kidney cortex destroys acetoacetic acid at a considerable rate,  $Q_{Ac}$ <sup>1</sup> reaching a value of  $-4.0$  with the guinea-pig and  $-6.0$  with the rat. In Table I the results of 20 experiments with each animal are reported. It will be seen that with an initial con-

Table I.

Sodium acetoacetate solution = 0.0058 *M*.

Ringer solution,  $NaHCO_3$  = 0.025 *M*. 95%  $O_2$  + 5%  $CO_2$ .

Tissue	Cyanide <i>M</i>	Glucose <i>M</i>	No. of exps.	Mean value of $-Q_{Ac}$	Range of values of $-Q_{Ac}$	Av. deviation from mean value
Guinea-pig kidney	Nil	Nil	20	3.4	1.9-4.8	$\pm 0.6$
"	Nil	0.009	6	3.6	2.5-4.2	$\pm 0.4$
"	0.004	Nil	9	1.4	0.6-1.9	$\pm 0.4$

<i><math>\beta</math>-Glycerophosphate <i>M</i>/15 buffer. <math>O_2</math>.</i>						
Guinea-pig kidney	Nil	Nil	4	3.9	2.5-4.5	$\pm 0.7$
Rat kidney	Nil	Nil	3	4.9	4.4-5.4	$\pm 0.4$

<sup>1</sup> As explained in an earlier paper, the symbol  $Q_{Ac}$ , when it has a positive value, expresses the rate of appearance of acetoacetic acid, and when it has a negative value, expresses the rate of disappearance of acetoacetic acid, as ml. of gas (at N.T.P.) per hour per mg. dry weight of tissue.

centration of sodium acetoacetate of 0.0058 *M* and at  $p_H$  7.4 in a bicarbonate-Ringer solution, the mean  $Q_{Ac}$  is -3.4 for guinea-pig kidney and -4.5 for rat kidney. There is a relatively large range of variation, the average deviation from the mean value being  $\pm 0.6$  and  $\pm 0.7$  respectively. It is likely that the state of nutrition of the animal plays an important part in determining the magnitude of  $Q_{Ac}$ . It should be noted however that in all experiments reported on here apparently well-nourished animals were used.

In  $\beta$ -glycerophosphate buffer in presence of oxygen, the breakdown of acetoacetic acid proceeds at much the same rate as in a bicarbonate-Ringer solution.

*Anaerobic breakdown of acetoacetic acid.*

Acetoacetic acid is broken down under anaerobic conditions by kidney tissue (see Part III). The results of a number of experiments with rat and guinea-pig tissues in presence of 95 %  $N_2$  + 5 %  $CO_2$  are shown in Table II. The rate of breakdown is roughly half that under aerobic conditions, but here again there is a fairly wide range of variation probably determined by nutritional conditions.

Table II.

Sodium acetoacetate solution = 0.0058 *M*.

Ringer solution,  $NaHCO_3$  = 0.025 *M*, 95 %  $N_2$  + 5 %  $CO_2$ .

Tissue	No. of exps.	Mean value $-Q_{Ac}$	Values of $-Q_{Ac}$ obtained
Guinea-pig kidney	4	2.4	2.7, 2.1, 2.8, 1.9
Rat kidney	8	2.3	2.1, 2.1, 2.1, 2.0, 2.8, 1.8, 2.1, 2.5

*Action of potassium cyanide on acetoacetic acid breakdown.*

Cyanide (0.004 *M*;  $p_H$  7.4) reduces acetoacetate breakdown by kidney under aerobic conditions to the anaerobic level. Values of  $-Q_{Ac}$  in presence of nitrogen are scarcely affected by cyanide at this concentration.

Table III. *Action of potassium cyanide on acetoacetate breakdown.*

Sodium acetoacetate solution = 0.0058 *M*.

Ringer solution,  $NaHCO_3$  = 0.025 *M*.

15	"	No cyanide		$Q_{O_2}$ = 25.2;	$-Q_{Ac}$ = 5.4

Moreover, the effect of cyanide is much the same in a  $\beta$ -glycerophosphate buffer as in a bicarbonate-Ringer solution. Typical results are shown in Table III. The results of a number of experiments with guinea-pig and rat kidneys are also shown in Table I. There it will be observed that the mean values of  $Q_{Ac}$ , in presence of cyanide, are definitely lower than those found in nitrogen. This is due to the fact that, in a number of early experiments, remarkably low figures for  $-Q_{Ac}$  for kidneys in presence of cyanide were found; such low figures were not subsequently encountered.

*Action of glucose on acetoacetic acid breakdown.*

A. *Under aerobic conditions.* Glucose, in a bicarbonate medium at  $p_H$  7.4 and in presence of 95%  $O_2$  + 5%  $CO_2$ , seems to have a small accelerating

action on the rate of breakdown of acetoacetic acid in kidney. The results of a number of experiments are shown in Table I and some typical figures are given in Table IV (see also Part III). The effect of glucose addition is real but obviously variable, depending on the activity of the tissue in absence of added glucose.

B. *Under anaerobic conditions.* Glucose has but little effect on the  $-Q_{Ac}$  found under anaerobic conditions (95 %  $N_2$  + 5 %  $CO_2$ ) with rat or guinea-pig kidney. Typical results are shown in Table IV.

C. *In presence of cyanide.* It will be seen from results given in Tables I and V that glucose accelerates acetoacetate breakdown in media containing potassium cyanide (0.004  $M$ ;  $p_H$  7.4), this acceleration obtaining whether conditions are aerobic or anaerobic. A close examination of the figures given in Table V shows however that the acceleration by glucose is only perceptible when the value of  $-Q_{Ac}$ , in absence of added glucose, is well below the normal anaerobic value (see Exps. 3, 4, 7, 8, 9, 11, 14, 15). Glucose addition seems to secure the value of  $-Q_{Ac}$  at some maximum value; should the tissue alone exhibit this value, the addition of glucose has little or no further effect.

*Action of pyruvic acid on acetoacetic acid breakdown.*

Pyruvic acid, at a concentration of 0.009  $M$ , behaves similarly to glucose. It has no appreciable effect, at this concentration, on  $-Q_{Ac}$  aerobically, but in presence of cyanide it will raise any abnormally low value of  $-Q_{Ac}$  to the normal anaerobic value of about 2.0. It seems to have no effect (anaerobically) on a tissue which gives this value in absence of added pyruvate.

The experiment was tried of adding a mixture of glucose and sodium pyruvate to the tissue. This, as is well known, secures conditions for maximum glycolysis under anaerobic conditions or in presence of cyanide. The addition of pyruvate (0.009  $M$ ) brings about relatively high values for  $-Q_{Ac}$  in presence of cyanide (see Tables VI and VII), but the rates of breakdown of acetoacetic acid are not abnormally high and are of the same order of magnitude as those obtained under normal anaerobic conditions. This work, as a whole, indicates that the presence of a mixture of glucose and pyruvate helps to establish more definitely the

optimum conditions for the rate of breakdown of acetoacetic acid under anaerobic conditions. The effects of varying the initial concentration of acetoacetate are shown in Table VII.

*$\beta$ -Hydroxybutyric acid production by guinea-pig kidney.*

It has already been shown (see Part II) that acetoacetic acid in the liver gives rise to  $\beta$ -hydroxybutyric acid. This transformation occurs also in the kidney. The results of a number of experiments carried out to determine the conditions effecting this transformation are shown in Table VIII. The rate of appearance of  $\beta$ -hydroxybutyric acid (expressed as ml. of gas at N.T.P. per hour per mg. dry tissue) is given by the symbol  $Q_{ox}$ .

Details of the micro-estimation (gravimetric) of  $\beta$ -hydroxybutyric acid are given in Part II. It is necessary in estimating  $\beta$ -hydroxybutyric acid production from acetoacetic acid in presence of glucose, cyanide *etc.* to carry out control estimations in absence of tissue. All figures quoted in Table VIII have been corrected for the “blanks”.

The following results are of note:

1. The value of  $Q_{oxy}$  under normal aerobic conditions is unaffected by the presence of glucose or of a mixture of glucose (0.009 *M*) and pyruvate (0.009 *M*) (Exps. 1, 2, 5).

2. The value of  $Q_{oxy}$  is definitely increased in presence of cyanide (0.004 *M*) (Exps. 3, 4, 5).

3. The addition of glucose, or of glucose together with pyruvate, to kidney tissue in presence of cyanide increases the value of  $Q_{oxy}$  (Exps. 5, 6, 7, 8). The value of  $Q_{oxy}$  may be increased under these conditions by as much as 100%. Moreover, under these optimum conditions for the breakdown (in presence of cyanide) of acetoacetic acid,  $Q_{oxy}$  becomes comparable with  $-Q_{Ac}$ , i.e. the breakdown of acetoacetic acid, under these conditions, can be almost quantitatively accounted for by transformation into  $\beta$ -hydroxybutyric acid.

It is clear from these results that glucose (or glucose + pyruvate) affects greatly the transformation of acetoacetic acid into  $\beta$ -hydroxybutyric acid, this being readily observed in the presence of cyanide when the respiration of the tissue is practically entirely eliminated.

Under normal aerobic conditions production of  $\beta$ -hydroxybutyric acid cannot account for more than one-quarter to one-third of the acetoacetic acid broken down; presumably most of the remainder of the acetoacetic acid broken down is oxidised to  $CO_2$  and  $H_2O$ .

*Effects of glutathione and ascorbic acid on acetoacetic acid breakdown by kidney.*

Results of the action of glutathione and ascorbic acid on acetoacetic acid breakdown are shown in Table IX.

Table IX. *Effects of glutathione and ascorbic acid on acetoacetate breakdown.*

\* Glucose added at a concentration of 0.009 *M*.

† Glucose (0.009 *M*) and HCN (0.004 *M*) added.

Under normal aerobic conditions the addition of glutathione to acetoacetic acid in presence of kidney causes little or no change in its rate of breakdown (Exps. 2, 7).

Under anaerobic conditions however the presence of glutathione causes a pronounced acceleration of the rate of disappearance of acetoacetic acid, this

being the case whether glucose is added or not. The presence of cyanide (Exps. 4, 6) does not diminish this effect of glutathione. In Exp. 6 an acceleration of the order of 100 %, due to glutathione, is recorded.

There can be no doubt from these results that the presence of glutathione in the tissue must be a factor contributing to the anaerobic disappearance of acetoacetic acid.

A few experiments carried out with ascorbic acid show no definite effect of this substance on the rate of anaerobic change of acetoacetic acid in the kidney (Exps. 4, 8, 9).

*Effects of added fatty acids on acetoacetic acid breakdown.*

The addition of sodium salts of fatty acids to kidney reduces the apparent rate of breakdown of acetoacetate. Only acetate, propionate and butyrate have been investigated so far and their effects are specially noticeable with guinea-pig kidney. The results are noted in Table X.

The inhibitory effects of acetate and butyrate (Exps. 1, 2, 11) might be explained as due to the ketogenic effects of these acids; for it would be expected that the enzyme dealing with acetoacetic acid would be saturated when in presence of the concentration of acetoacetate used in these experiments and hence would not be able to deal effectively with any acetoacetic acid produced by acetic and butyric acids.

The inhibitory effects of propionate (Exps. 6, 7, 9) cannot however be explained in this way: the explanation for this inhibition must await further investigation.

It is of interest that the propionate inhibition which is so pronounced with guinea-pig kidney seems only to occur at relatively high concentrations with rat kidney (Exp. 8).

Under anaerobic conditions, or in presence of cyanide, the inhibitions of acetate, propionate and butyrate are diminished or eliminated (Exps. 4, 5, 10, 12).

*Effect of malonic acid on acetoacetic acid breakdown.*

It was shown in the preceding paper (Part III) that the presence of malonate increases the rates of spontaneous acetoacetic acid production by rat and guinea-pig livers. It will now be shown that malonate exerts a large inhibitory effect on the breakdown of acetoacetic acid in the presence of rat kidney.

Typical results are shown in Table XI. Four experiments demonstrating the action of 0.016 *M* malonate are shown in Series 1, and another four demonstrating the action of 0.008 *M* malonate in Series 2. The former concentration of

malonate gives an average inhibition of 63%, the latter of 42%, of the rate of breakdown of acetoacetate with rat kidney. This effect occurs only aerobically, there being little inhibitory effect of malonate in presence of nitrogen (Exp. 1, Table XI). A similar inhibitory action of malonate occurs also with rat liver (Exp. 2), and doubtless this phenomenon explains the action of malonate in apparently increasing acetoacetic acid formation with liver slices (see Part III).

Some possible interpretations of the malonate inhibition of aerobic acetoacetic acid breakdown may now be considered.

The first obvious possibility is that malonate competes with acetoacetic acid for the enzyme involved, just as it has been shown [Quastel and Wooldridge, 1928] that malonate competes with succinate for succinic dehydrogenase. It is unlikely, however, that this view is wholly correct because the addition of sodium fumarate to the acetoacetate-malonate system partially neutralises the malonate effect (Exps. 1, 2, Table XII). Should it be held that the alleviating action of

fumarate is due to its competition with malonate for the acetoacetic enzyme, then it follows that fumarate itself should inhibit acetoacetate breakdown. This does not occur; in fact, fumarate exercises a very slight accelerating action (Exps. 1, 2, Table XII).

The next possibility is that acetoacetate oxidation is accomplished by a succinic-fumaric-oxaloacetic system acting catalytically in the sense described by Szent-Györgyi and his colleagues [1935]. On this view acetoacetate would be oxidised by oxaloacetate, the latter molecule becoming reduced to fumarate and succinate. These substances would re-form oxaloacetate under normal aerobic conditions. In the presence of malonate, the oxidation of succinate is inhibited and therefore the succinic-oxaloacetic system is no longer reversible; such oxaloacetic or fumaric acid as is present in the tissue becomes ultimately reduced to succinic acid. In this manner malonate would be held to inhibit the oxidation of acetoacetate. Addition of fumarate neutralises the malonate inhibition simply by re-forming the fumaric-oxaloacetic system.

According to this theory, no substance should neutralise the malonate inhibition except one which gives rise to the succinic-fumaric-oxaloacetic catalytic system. Thus it might be expected that the addition of malic or aspartic acid (which gives rise to oxaloacetic acid on oxidation) would neutralise the malonate effect. But it would not be expected that substances such as lactic acid or alanine could accomplish such a neutralisation. This, however, is what in fact occurs. Exps. 3, 4, 5, 6, 8, Table XII show that both lactate and alanine in a Ringer medium diminish the malonate inhibition; neither of these substances shows any marked acceleration of acetoacetate breakdown in the absence of malonate.

Such results as these do not mean, of course, that the second possibility, just outlined, is incorrect; but they do mean that a separate explanation would have to be found for the partial neutralising effects of lactate or alanine. Our experiments on this point are so far not very numerous, but sufficient perhaps has been done to justify our putting forward the following suggestion.

Let us assume that the oxidation of acetoacetate in the tissue under aerobic conditions is a coupled one, the reaction depending on the oxidation of other substrates in the cell. The assumption may also be made, in order to give definition to this view, that the coupling is effected in the cell by hydrogen peroxide this substance being normally produced in the oxidation of cell substrates. We have then the following processes:

- (1) cell substrates +  $O_2 \rightarrow H_2O_2$  + products of substrate oxidation,
- (2) acetoacetic acid +  $H_2O_2 \rightarrow$  oxidation products of acetoacetic acid.

In presence of a given concentration of acetoacetate the velocity of process (2) will be determined by the amount of "active" oxygen supplied by the hydrogen peroxide after activation by its appropriate enzymes (peroxidase, catalase). It is not unreasonable to suppose that when the cell is working under optimum aerobic conditions the enzymes dealing with hydrogen peroxide are saturated and process (2) proceeds at a constant rate. The addition of further oxidisable substrates which might increase the available amount of  $H_2O_2$  in the cell would not necessarily increase the rate of process (2). If however a substance is added to the cell which diminishes the velocity of process (1), it follows that the amount of  $H_2O_2$  produced may fall below the saturation concentration of its activating enzyme and the velocity of process (2) will diminish. The addition to the cell, at this point, of substances restoring the velocity of process (1) should also have the effect of restoring the velocity of process (2).

This view seems to account for the facts obtained so far. Lactate, alanine and fumarate raise the respiration of kidney slices and therefore may, as possible  $H_2O_2$  formers, neutralise, or partially neutralise, malonate inhibition. Glucose, which seems not to affect markedly the respiration of kidney, has but little neutralising effect on malonate inhibition at the concentration at which it has been tried (Exps. 7, 8, Table XII).

#### *Effect of benzoic acid on acetoacetic acid breakdown.*

Sodium benzoate is a much more vigorous inhibitor of acetoacetate breakdown in the guinea-pig kidney than in rat kidney. A few typical results are shown in Table XIII. It will be observed that with guinea-pig kidney, 0.005 *M* sodium benzoate brings about 40 % inhibition of the rate of breakdown of acetoacetate (Exp. 4). Under anaerobic conditions this concentration of benzoate has but little effect.

It is of interest that the inhibitory action of benzoate on acetoacetic acid decomposition is considerably smaller than on the oxidation of the lower fatty acids by liver (see Part II).

*Effects of iodoacetic and arsenious acids on acetoacetic acid breakdown.*

Both iodoacetate and arsenite greatly inhibit the decomposition of acetoacetic acid by kidney. Typical results are shown in Table XIV. Arsenite at a concentration of  $2.5 \times 10^{-4}$  *M* inhibits the breakdown of acetoacetic acid in guinea-pig kidney by over 70%, and iodoacetate at a concentration of  $3.3 \times 10^{-4}$  *M* brings about an inhibition of the same order.

Table XIV. *Action of iodoacetic and arsenious acids on acetoacetic acid breakdown.*

*Effects of minced kidney and of kidney extracts on acetoacetic acid breakdown.*

It is of interest that the effect of mincing kidney (rat or guinea-pig) is to diminish but not to eliminate acetoacetate decomposition. The following results were obtained:

Acetoacetate concentration = 0.0058 *M*. Ringer solution, 95 %  $O_2$  + 5 %  $CO_2$ .

		- $Q_{Ac}$
Rat kidney	Intact slices	4.7
	Minced tissue	2.9
Guinea-pig kidney	Intact slices	3.8
	Minced tissue	1.3

On making an extract of kidney, by grinding it with sand in four times its volume of *M*/50 phosphate buffer ( $p_H$  7.4) and centrifuging, it was found that the opalescent centrifugate possessed some power of breaking down acetoacetic acid. The following results were obtained with rat kidney:

Exp.	ml.		$O_2$ consumed in 2 hr. (37°) $\mu$ l.	Acetoacetic acid found after 2 hr. $\mu$ l.
1	2	Kidney extract	134.9	Nil
	2	Kidney extract + acetoacetate (377 $\mu$ l.)	162	324
<i>i.e.</i> increase in $O_2$ uptake = 27.1 $\mu$ l. and acetoacetate decomposed = 53 $\mu$ l.				

Exp.	ml.		$O_2$ consumed $\mu$ l.	Acetoacetic acid found $\mu$ l.
2	2	Kidney extract	118	Nil
	2	Kidney extract + acetoacetate (379 $\mu$ l.)	143	322
<i>i.e.</i> increase in $O_2$ uptake = 25 $\mu$ l. and acetoacetate decomposed = 57 $\mu$ l.				

## DISCUSSION.

It is obvious from the facts given in this paper that acetoacetic acid undergoes at least two changes in the kidney:

- (a) an anaerobic transformation;
- (b) an aerobic oxidation.

The two processes are quite distinct as is clear from the fact that inhibitors (*e.g.* malonate, propionate, benzoate, cyanide), which may greatly affect the aerobic change, have but little effect on the anaerobic change.

The anaerobic change consists principally of a transformation into  $\beta$ -hydroxybutyric acid; this is shown by the fact that kidney, in presence of cyanide and glucose, shows a production of  $\beta$ -hydroxybutyric acid which is of the same order as the rate of breakdown of acetoacetic acid. The anaerobic process of breakdown or the process in presence of cyanide is accelerated to some extent by glucose and to a larger extent by glutathione. The rates of aerobic breakdown of acetoacetic acid are not nearly so much affected either by glucose or by glutathione. This may be explained partly by the fact that  $\beta$ -hydroxybutyric acid is oxidised by kidney; a few experiments with guinea-pig kidney have indicated that the rate of breakdown of  $\beta$ -hydroxybutyric acid is of the same order as that of acetoacetic acid.<sup>1</sup> We may assume that normally in the kidney cell there exists an equilibrium between acetoacetic and  $\beta$ -hydroxybutyric acids. This equilibrium is determined on the one hand by the source of active hydrogen (glucose, pyruvate, glutathione) and on the other hand by the supply of active oxygen.

<sup>1</sup> The facts given in this paper do not invalidate the possibility that acetoacetic acid may only suffer oxidation after prior reduction to  $\beta$ -hydroxybutyric acid.

It is of particular interest that glutathione should markedly affect the rate of anaerobic transformation of acetoacetic acid. The fact that no stimulation occurs aerobically may be taken to mean that the effect of the glutathione is not due to an activation of the enzyme concerned with acetoacetic acid breakdown, and it is likely therefore that the anaerobic effect is due to a reduction of ketonic acid by the sulphhydryl compound. Should this be confirmed by further experiment, the phenomenon will provide an interesting example of the participation of glutathione in a ketonic acid-hydroxy-acid equilibrium.

Production of  $\beta$ -hydroxybutyric acid does not account for more than one-quarter to one-third of the acetoacetic acid broken down under aerobic conditions. The rest of the acetoacetic acid broken down is probably mostly oxidised to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . This oxidation is, in the rat kidney, greatly inhibited by the addition of malonate and the malonate inhibition is neutralised, or partly neutralised, in a Ringer medium, by the further addition of substances burned by the kidney. Such substances are fumarate, lactate and alanine. Glucose, which does not increase kidney respiration appreciably, does not neutralise the malonate inhibition. It is suggested that an explanation of these facts lies in assuming that the oxidation of acetoacetate is a coupled one, the reaction depending on the oxidation of other cell substrates. Granting the truth of this assumption, which explains adequately the facts in this paper, there seems no reason to adopt the view that malonate inhibition of acetoacetate breakdown might be due to the inhibition of a succinic acid catalytic system. Such a view will not explain the neutralising effects of lactate and alanine.

That the malonate inhibition may be due to the inhibition of a process involving succinic acid formation and oxidation seems feasible, but that it should be taken to indicate the presence of a catalytic system controlling the entire respiration of the tissue is doubtful, if only because of the facts already cited. It has already been pointed out [Jowett and Quastel, 1935, 3] that malonate acts very differently on the respirations of guinea-pig liver and rat liver and a similar difference occurs with the kidneys. Malonate inhibition of acetoacetate breakdown is considerably less at the concentrations tried with guinea-pig kidney than with rat kidney.

#### SUMMARY.

1. Acetoacetic acid is broken down under both aerobic and anaerobic conditions by rat and guinea-pig kidneys (cortex slices).
2. The presence of cyanide reduces the rate of aerobic breakdown of acetoacetic acid to the anaerobic level.
3. Production of  $\beta$ -hydroxybutyric acid accounts for only one-third to one-quarter of the acetoacetic acid decomposed under aerobic conditions. The presence of cyanide increases  $\beta$ -hydroxybutyric acid production, and the rate of the latter in presence of cyanide is increased by addition of glucose, or of a mixture of glucose and sodium pyruvate.
4. The anaerobic transformation of acetoacetic acid is greatly increased by the addition of glutathione but not by ascorbic acid. The aerobic change is unaffected by glutathione.
5. Salts of acetic, propionic and butyric acids inhibit aerobic oxidation of acetoacetic acid (guinea-pig kidney). They have little effect on the anaerobic process.
6. Sodium malonate greatly inhibits aerobic oxidation of acetoacetic acid (rat kidney). This inhibition may be neutralised, or partially neutralised, when experiments are carried out in a Ringer medium by the addition of sodium

fumarate, sodium lactate or alanine. It is suggested that the oxidation of acetoacetic acid is a coupled one, depending upon the oxidation of other cell substrates.

7. Benzoic acid has a much greater inhibitory effect on acetoacetate breakdown in presence of guinea-pig kidney than in presence of rat kidney. Iodoacetic and arsenious acids are highly inhibitory.

8. Minced kidney and kidney extracts show an ability to break down acetoacetic acid.

One of us (A. H. M. W.) is grateful to the Medical Research Council for a whole time grant. The thanks of both of us are due to this body for a grant in aid of equipment.

# CCCXXXI. URICASE AND ITS ACTION.

## VIII. EXTRACTION AND PRECIPITATION OF OX KIDNEY URICASE.

By RICHARD TRUSZKOWSKI AND SZEJNA GUBERMANÓWNA.

*From the Biochemical Laboratory, Medical Faculty, Warsaw University.*

*(Received October 25th, 1935.)*

### EXTRACTION.

#### *Experimental methods.*

*Preparation of uricase.* Uricase was in some cases prepared according to the method described in Part VII [Truszkowski, 1934] (this will be termed Method I). The following procedure (Method II), which has the merits of economy of material, time and labour, was later adopted. The extracts are more highly coloured than are those of uricase prepared by the previous method, but for many purposes they serve equally well.

Minced ox kidney was placed in a 10-litre bottle, and cold water, entering the bottle through a tube reaching to the bottom, was run through until the supernatant liquid became quite clear and colourless. The residual tissue, freed in this way of its soluble constituents as well as of smaller insoluble particles, was dried at 37° in a current of air, and the dry residue was ground to an impalpable powder in a mill. The yellow powder so obtained exhibits considerable uricolytic activity, and on extraction with aqueous  $\text{Na}_2\text{CO}_3$  affords deep yellow, active extracts, often possessing a disagreeable odour. The quality of the product is greatly improved by repeated washing on a Büchner funnel with 96% alcohol at room temperature, followed by ether; the washing is continued until the filtrate becomes colourless. The residue is then washed four times with anhydrous alcohol-free ether, spread in a thin layer and dried at 30° under reduced pressure. The dry uricase so obtained is a light yellow powder, which can be stored for many months without deterioration, provided that traces of solvent (water, alcohol, ether) are absent, and that undue exposure to the air is avoided. The yield is roughly 100 g. per kg. of kidneys.

Solutions of uric acid were prepared by adding uric acid to boiling aqueous NaOH (65 ml. of 0.1 N NaOH per g. of uric acid). The solutions so obtained had  $p_{\text{H}}$  8.6–9.0. Uric acid was determined colorimetrically by the method of Folin and Denis.

*Standardisation of conditions of determination of activity of uricase.* 10 flat-bottomed test-tubes (of uniform calibre), containing various volumes of a mixture of uric acid and uricase solutions and 0.5 ml. each of toluene, were kept at 37° for 48 hours, the contents of the tubes were mixed once by inversion, and uric acid was determined.

The results, given in Table I, indicate that the apparent activity of the uricase diminishes at first rapidly, and then more slowly, with increasing height of the column of the solution. Since the only difference between the systems consists in the supply of oxygen to the lower layers of solution, it may be concluded that dissolved oxygen in the body of the systems is rapidly consumed, and that further oxidation can take place only at the expense of fresh oxygen diffusing into the

Table I. *Effect of varying the volume of the systems on the apparent activity of uricase.*

Initial concentration of uric acid is 0.11%.

Height of column of solution cm.	Volume of system ml.	mg. of uric acid after 48 hours at 37° in whole system	
		Initially present	Oxidised
1.2	1.7	1.87	1.87
3.5	5.6	6.16	4.78
5.8	9.5	10.45	4.93
7.3	12.0	12.1	4.76
9.2	15.1	16.61	5.01
11.1	17.6	19.36	5.81
12.7	21.4	23.54	4.28
14.4	23.9	26.29	4.78
16.3	27.7	30.47	5.07
19.6	32.6	35.86	4.71

liquid from the atmosphere. This oxygen is, however, used up in the upper layers of solution as fast as it diffuses into the liquid, with the result that, after a time, a zone forms in which uric acid is completely oxidised, whilst the lower layers, being under practically anaerobic conditions, remain unchanged. Obviously, the thickness of the "oxidised layer" will increase with time, but this process, being dependent on diffusion of uric acid to the upper and of oxygen to the lower layers, is relatively extremely slow.

In the experiment described in Table I it will be observed that, except in the first test-tube, the total amount of uric acid oxidised is approximately constant in all the systems, the mean value being 4.9 mg. This would represent almost entirely uric acid oxidised in the upper zone and corresponds with a depth of 2.72 cm. for the zone in question.

It follows from the above experiments that care should be taken, in comparing the activities of different samples of uricase, that the total volume of solution should be the same in all cases, and that the containers should as far as possible be of the same shape and size. A further consequence of the above mechanism is that, even under strictly comparable conditions, the amount of uric acid oxidised will not necessarily be directly proportional to the concentration of uricase, *i.e.*, that the apparent activity of a given preparation may vary, according to its relative concentration.

The following experiment illustrates this point. 0.5–3 ml. of uricase solution were added to a number of flasks containing 10 ml. of 0.1% uric acid, and 0.16%  $\text{Na}_2\text{CO}_3$  was added to make the volume up to 13 ml. in all the systems, which were then incubated at 37° for 18 hours, and uric acid was determined. The results (Table I *a*) indicate that the number of mg. of uric acid oxidised per

Table I *a*. *Activity of a given preparation of uricase taken in different concentrations.*

All systems contain initially 10.81 mg. of uric acid.

Volume of uricase taken ml.	mg. of uric acid		
	In system	Oxidised	Oxidised per ml. of uricase
0.5	7.26	3.55	7.1
1.0	5.08	4.83	4.83
1.5	4.6	6.21	4.14
2.0	3.45	7.36	3.68
3.0	2.1	8.71	2.9

ml. of uricase solution varies from 7.1 when 0.5 ml. of preparation are taken to 2.9 when 3 ml. are present.

It was shown in Part IV of this series [Truszkowski, 1930] that the activity of insoluble preparations of uricase varies widely with the  $p_H$  of the medium, and that the optimum  $p_H$  is about 9.0. Identical results were obtained for dissolved uricase.

On the basis of the foregoing, the following standard conditions for the determination of the activity of uricase were adopted. The systems should consist of 10 ml. of 0.1–0.2% uric acid solution, 1 ml. of uricase solution and 0.5 ml. of toluene, in 100 ml. Erlenmeyer flasks, which should be as far as possible of uniform shape. The addition of buffer solution is not necessary, since systems prepared as above are of a suitable  $p_H$ . Determinations may be made after any time of incubation at 37°; usually 18 hours will be the most convenient time.

*Determination of optimum conditions of extraction.*

*Concentration of  $Na_2CO_3$ .* Ro [1931] found that the most active extracts are obtained using 0.125%  $Na_2CO_3$ . The experiments described below indicate that the optimum concentration of alkali varies according to the preparation of dry uricase taken and should be determined separately in each case (Table II).

0.2 g. portions of dry uricase were kept for 48 hours at 37° with 20 ml. portions of 0.03–0.2%  $Na_2CO_3$  and 1 ml. of toluene, the suspensions were filtered, 1 ml. of filtrate was added to 10 ml. of uric acid solution, and uric acid was determined after 18 hours at 37°.

Table II. *Dependence of activity of uricase solution on the  $Na_2CO_3$  concentration.*

All flasks contain 10 ml. of uric acid, 1 ml. of extract and 0.5 ml. of toluene.

Nature of preparation	Concentration $Na_2CO_3$ %	$p_H$		mg. uric acid after 18 hours at 37°

	0.12	—	—	8.8	8.56
	0.16	—	—	8.8	8.8
Ox kidney (Method I)	0.2	—	—	8.8	8.6
	0.04	9.5	7.7	5.9	1.7
	0.08	10.1	8.7	5.9	4.2
	0.12	10.34	9.42	5.9	4.2
	0.16	10.38	9.56	5.9	3.6
	0.2	10.51	9.37	5.9	3.5

The results given in Table II indicate that the strength of the extracts first rises as the concentration of  $Na_2CO_3$  increases and then falls. This effect is

interpreted as being the resultant of two opposed processes; dissolution of some substance of an acidic nature, and denaturation by alkali.

It was thought, in view of the above, that more active extracts might be obtained by adding the  $\text{Na}_2\text{CO}_3$  gradually during the course of the extraction; this possibility was investigated in two ways. In one, the concentration of the  $\text{Na}_2\text{CO}_3$  was kept constant, but its volume was gradually increased; 0.5 g. of uricase (Method I) was allowed to stand at  $37^\circ$  for 18 hours with 10 ml. of 0.08 %  $\text{Na}_2\text{CO}_3$ , a further 10 ml. portion of which was added after 25 hours and 20 ml. after 42 hours. 2 ml. of the extract obtained after 48 hours added to 10 ml. of 0.06 % uric acid solution oxidised 1.8 mg. of uric acid after 20 hours at  $37^\circ$ ; under comparable conditions, 2 ml. of the extract obtained when 0.5 g. of uricase was kept for 48 hours with 50 ml. of 0.08 %  $\text{Na}_2\text{CO}_3$  oxidised 4.5 mg. of uric acid.

The experiment was repeated maintaining the volume of the solution constant, but progressively increasing its concentration; 100 ml. of 0.03 %  $\text{Na}_2\text{CO}_3$  were added to 1 g. of uricase, five 0.01 g. portions of  $\text{Na}_2\text{CO}_3$  were added at intervals during 52 hours, to bring the final concentration to 0.08 %; 2 ml. of the filtrate obtained after 48 hours of incubation oxidised 3.0 mg. of uric acid. No advantage is therefore gained by varying the concentration or amount of  $\text{Na}_2\text{CO}_3$  during extraction.

*Extraction by other solutions.* The activity of the extracts obtained using solutions of  $\text{K}_2\text{CO}_3$ , NaOH and glycine-NaOH buffers (Sørensen) was investigated.

1 % solutions of  $\text{K}_2\text{CO}_3$ , NaOH and  $\text{Na}_2\text{CO}_3$  were added to water to bring the  $p_{\text{H}}$  to 9.65, 0.2 g. of uricase (Method I) was added to 20 ml. portions of the solutions, the suspensions were filtered after 48 hours at  $37^\circ$  and their uricolytic activity and final  $p_{\text{H}}$  value determined. (2 ml. of uricase, 10 ml. of 0.078 % uric acid). A series of Sørensen's glycine-NaOH buffer solutions (30 ml. portions,  $p_{\text{H}}$  7.59–10.2) was prepared, 0.3 g. of uricase added to each portion and the activity of the extracts determined. Finally, 2 g. of uricase were extracted as above with 100 ml. of 0.1 %  $\text{Na}_2\text{CO}_3$  or of 5 % NaCl and the activity of the extracts determined.

Table III. *Activity of extracts prepared from uricase and aqueous  $\text{K}_2\text{CO}_3$ , NaOH and glycine-NaOH buffer solution.*

All flasks contain 10 ml. of uric acid, 2 ml. of extract or extractive solution and 0.5 ml. of toluene.

Nature of extractive solution	$p_{\text{H}}$		mg. uric acid after 18 hours at $37^\circ$		
	Initial	Final	In control	In system	Oxidised
$\text{Na}_2\text{CO}_3$	9.65	8.11	7.8	3.6	4.2
$\text{K}_2\text{CO}_3$	9.65	7.74	7.8	5.8	2.0
NaOH	9.65	6.23	7.8	7.5	0.3
Sørensen's buffers	7.59	—	6.0	5.9	0.1
	7.96	—	6.0	5.4	0.6
	8.68	—	6.0	5.4	0.6
	9.07	—	6.0	4.1	1.9
	9.35	—	6.0	3.0	3.0
	9.5	—	6.0	1.7	4.3
	9.87	—	6.0	2.9	3.1
	10.06	—	6.0	5.9	0.1
	10.2	—	6.0	6.0	0

The results, given in Table III, indicate that the activity of the extracts depends not only on the initial, but also on the final  $p_{\text{H}}$ . Thus NaOH is an unsatisfactory solvent owing to the circumstance that the highest concentration

possible without inactivation represents a small amount of base, rapidly neutralised by the acidic constituents of the dry uricase, with the result that the solution becomes actually acid. In conjunction with glycine, NaOH extracts are fully as active as are those with  $\text{Na}_2\text{CO}_3$  (at  $p_{\text{H}}$  9.5). It would follow that the essential conditions for successful extraction are that the initial  $p_{\text{H}}$  be  $> 9.5-9.6$ , and the final  $p_{\text{H}}$   $< 8.0$ ; any alkaline solution fulfilling these conditions would be an equally satisfactory solvent.

*Optimum proportion of dry uricase.* A further conclusion to be drawn from the above experiments is that the relative concentration of dry uricase taken for extraction cannot vary beyond certain narrow limits, determined by the necessity of maintaining the  $p_{\text{H}}$  between 9.5 and 8.0. As is shown by the following experiment, it is not possible to obtain extracts much more active than those described above by increasing the relative amount of dry uricase.

A number of 0.5 g. portions of uricase (Method I) were extracted with 50, 40, 30, 20 and 10 ml. portions of 0.08 %  $\text{Na}_2\text{CO}_3$  ( $p_{\text{H}}$  9.84) (48 hours at  $37^\circ$ ), and the activity of the filtrates was determined.

Table IV. *Effect of varying the relative proportions of dry uricase on the activity of the extracts.*

All flasks contain 10 ml. of 0.075 % uric acid, 2 ml. of uricase and 0.5 ml. of toluene.

Relative proportion of dry uricase (%)	Final $p_{\text{H}}$	mg. of uric acid after 18 hours at $37^\circ$		
		In control	In system	Oxidised
0.5	9.36	7.5	6.9	0.6
1.0	8.69	7.5	4.4	3.1
1.5	8.60	7.5	2.9	4.6
2.0	8.5	7.5	2.0	5.5
2.5	8.4	7.5	1.9	5.6

The results (Table IV) show that no advantage is gained by taking more than 2 g. of dry uricase per 100 ml. of solution, and that the final  $p_{\text{H}}$  falls progressively.

#### *Temperature of extraction.*

2 % suspensions of dry uricase (Method II) in 0.16 %  $\text{Na}_2\text{CO}_3$  were maintained at  $37^\circ$  and  $20^\circ$ , and the activity of the suspensions and of their filtrates was determined after 24 and 48 hours.

Table V. *Activity of suspensions and extracts after incubation at  $37^\circ$  and at  $20^\circ$ .*

All flasks contain 10 ml. of uric acid, 0.3 ml. of suspension + 0.7 ml. of  $\text{H}_2\text{O}$ , or 1 ml. of extract and 0.5 ml. of toluene.

Temperature ( $^\circ$ )	Time hours	Preparation studied	mg. uric acid after 20 hours at $37^\circ$			
			In control	In system	Oxidised	Oxidised per ml. of preparation
—	0	Suspension	8.2	2.1	6.1	20.3
37	24	Suspension	8.7	5.9	2.8	9.3
		Filtrate	8.7	2.4	6.3	6.3
	48	Suspension	8.7	5.7	3.0	10.0
		Filtrate	8.7	3.2	5.5	5.5
20	24	Suspension	8.7	4.8	3.9	13.0
		Filtrate	8.7	2.4	6.3	6.3
	48	Suspension	8.7	4.5	4.2	14.0
		Filtrate	8.7	1.9	6.8	6.8

The results (Table V) indicate that about 50 % of the activity of the suspension is lost after incubation at 37° for 24 or 48 hours, as compared with about 34 % at 20°. The extracts possess equal activities after 24 hours, whilst after 48 hours the 20° extract is the more active.

It follows that extraction at room temperature is more advantageous than at 37°, and that considerable inactivation of uricase takes place during the process of extraction.

*Duration of extraction.*

A suspension of 2 g. of uricase (Method II) in 100 ml. of 0.16 %  $\text{Na}_2\text{CO}_3$  was kept at room temperature (10–16°) for six days, and the activity of a sample of the well-mixed suspension and of its filtrate was determined daily.

Table VI. *Variation of activity of suspensions and extracts with time (room temperature).*

All flasks contain 10 ml. of 0.115 % uric acid, 0.3 ml. of suspension + 0.7 ml. of  $\text{H}_2\text{O}$ , or 1 ml. of filtrate or suspension and 0.5 ml. of toluene.

Preparation	mg. uric acid oxidised after 24 hours at 36° per 1 ml. of preparation, taken after					
	0	24	48	72	96	144 hours
Suspension	12.7	7.3	8.6	7.6	6.3	6.1
Filtrate	—	6.0	7.5	7.5	6.3	5.8

The results (Table VI) indicate that the activity of the extracts is at a maximum when the time of extraction at room temperature is 48–72 hours.

*Stability of extracts.*

An extract ( $p_{\text{H}}$  8.7) of 1 g. of dry uricase (Method I) in 0.08 %  $\text{Na}_2\text{CO}_3$  ( $p_{\text{H}}$  9.84) was kept at 37° in a stoppered flask with toluene for one month, and its activity was tested at intervals. The results, given in Table VII, indicate that the activity does not change during the first 4 days, is still considerable after 7 days, and falls to zero after 36 days.

Table VII. *Stability of extracts of uricase.*

All flasks contain 10 ml. of uric acid solution, 2 ml. of uricase and 0.5 ml. of toluene.

Time elapsed after filtration of extract (days)	mg. uric acid after 20 hours at 37°		
	In system	In control	Oxidised
0	1.7	5.8	4.1
4	1.7	5.8	4.1
6	2.2	5.8	3.6
7	2.2	5.8	3.6
12	3.2	5.8	2.6
20	3.1	4.6	1.5

PRECIPITATION.

*Precipitation by acetic acid.*

On gradual addition of 1 % acetic acid to the clear extract of uricase the solution becomes progressively more turbid, and, at the point of maximum turbidity a voluminous, flocculent precipitate separates, leaving a clear, light

yellow supernatant liquid when centrifuged or allowed to settle. Further addition of acid leads to the re-dispersion of the precipitate, to yield finally an opalescent solution, addition of 0.2%  $\text{Na}_2\text{CO}_3$  to which leads to the same changes, in the inverse order.

This preliminary experiment indicates that some amphoteric substance is present, and that its precipitation takes place at the isoelectric point.

*Conditions of precipitation of uricase.*

*Acetic acid.* The following experiments show that the activity of the precipitate rises with increase in the quantity of acid added to a maximum, corresponding with the point of maximum turbidity; the activity of the centrifugate falls continuously, whilst both the precipitate and the centrifugate are inactivated by addition of excess of acid.

A 2% suspension of dry uricase in 0.16%  $\text{Na}_2\text{CO}_3$  was filtered after 24 hours at  $37^\circ$ , 2 ml. of the filtrate were added to 10 ml. of 0.1% uric acid, and uric acid was determined after 20 hours at  $37^\circ$ . Various volumes (0.6–2.0 ml.) of 2% acetic acid were added to 10 ml. portions of the filtrate in 15 ml. centrifuge tubes, 2 ml. of the resulting suspensions were taken for determination of activity as before, the suspensions were centrifuged, the precipitates suspended in the same volume of water as that of the suspensions before centrifuging, and 2 ml. of the suspensions and centrifugates were taken for determination of activity. The N contents of the various fractions were determined, and the  $p_{\text{H}}$  of the centrifugates. The results, given in Table VIII, are corrected for the volume changes involved in adding acetic acid; thus 2 ml. of the original filtrate are equivalent to 2.2 ml. of the suspension obtained by adding 1 ml. of acetic acid to 10 ml. of filtrate, and the N content and number of mg. of uric acid oxidised were accordingly multiplied by 1.1.

The clear filtrate becomes turbid after addition of 0.6 ml. of 2% acetic acid, but no precipitate forms; for this reason the activity of the centrifugate is equal to that of the suspension. At the same time, it appears that the activity of the preparation is not diminished (apparently even enhanced) by addition of acetic acid to  $p_{\text{H}}$  7.89 and 7.48. At  $p_{\text{H}}$  7.48 a precipitate forms, of low activity. The most active precipitate is obtained at  $p_{\text{H}}$  6.96, but the activity of the suspension is somewhat lower than that of the original filtrate, and that of the centrifugate considerably more so. The activity of all fractions falls rapidly with increasing acidity, approaching zero when 1.0 ml. of 2% acetic acid per 10 ml. of filtrate is present. It will be seen that in this case the activity of the suspension is considerably greater than that of the precipitate, whilst the centrifugate is completely inactive; this apparent discrepancy may be ascribed to the shorter duration of action of acetic acid for the suspension as a whole (13 min.), than for the precipitate and centrifugate before samples were taken for testing activity (about 60 min. necessary for counterpoising and centrifuging the suspensions). Activity is practically nil with 1.4 ml. of acid and is totally absent at higher acidities.

The original N content corresponds to 0.668 mg. per 2 ml. of filtrate: on progressive addition of acid the N distributes itself in the approximate ratio of 3.5:1 in the centrifugates and precipitates. The activity, calculated per mg. of N, rises for the precipitates to a maximum for 0.8 ml. of acid ( $p_{\text{H}}$  6.96), thereafter falling below the original figure; the greatest increase in activity is almost exactly three-fold. It is of interest that most of the precipitate-N is obtained at  $p_{\text{H}}$  7.48; it is probable that this consists largely of inert material together with a small

amount of adsorbed uricase. Precipitation is not complete at the  $p_H$  at which inactivation commences.

The chief conclusions to be drawn from the above results are that the filtrates contain a mixture of active and inactive substances; about a third of the protein constituents is precipitable by acetic acid, and the precipitate consists chiefly of originally inactive substances, in addition to those inactivated by the acid. The remaining active constituents are, however, present in a concentration roughly three times greater than in the original filtrate proteins. The active principle is extraordinarily susceptible to acids, slight inactivation being observable at a  $p_H$  little different from that of neutrality, and practically total inactivation at  $p_H < 5.8$ .

A more direct comparison of the activities of the various preparations was effected in the following way. 4 g. of dry uricase (Method II) were suspended in 200 ml. of 0.16 % Na<sub>2</sub>CO<sub>3</sub>; the activity of the suspension was determined immediately, and after 24 hours at 37°; it was then filtered, 14 ml. of 2 % acetic acid were added to 130 ml. of filtrate, 18 ml. of the resulting suspension were placed in a centrifuge-tube and together with the remainder centrifuged. The precipitate from the first tube, representing one-eighth of the original 130 ml. of filtrate was dissolved in 16 ml. of 0.16 % Na<sub>2</sub>CO<sub>3</sub>, and the activity of the solution was determined. The remaining residues (representing seven-eighths of the original filtrate) were combined, washed 3 times on the centrifuge with 96 % alcohol and 3 times with dry, alcohol-free ether, and dried in a vacuum oven at 30°, 40 mg. of a white powder being obtained. The powder was dissolved in 28 ml. of 0.04 % Na<sub>2</sub>CO<sub>3</sub>, and its activity was determined.

The results are given in Table IX. The figures relating to the number of mg. of preparation present in the systems were arrived at as follows: (Exp. 1) 0.3 ml.

Table IX. *Relative activity of various preparations of uricase.*

All systems contain 10 ml. of uric acid solution.

No. of Exp.	Nature and amount of urico-lytic prep.	mg. of urico-lytic prep. present	mg. uric acid after 20 hours at 37°					Rel. activity	Fraction of original activity
			In control	In system	Oxidised

6	2 ml. of solution of dry precipitate	2.86	6.96	3.24	3.72	1.86	1.30	2	0.035

of suspension was taken containing 6 mg. of powder: (Exp. 2) 1 ml. containing 20 mg. of powder: (Exp. 4) seven-eighths of the filtrate, representing  $13/20$  of the total extract, yielded 40 mg. of dry precipitate, whence it follows that the whole 200 ml. of solution would have yielded 70.2 mg., and that the 1 ml. of dissolved precipitate contained 0.35 mg. of dry preparation: (Exp. 6) the 2 ml. of solution of the dry residue taken contained  $40 \times 2/28 = 2.86$  mg. of preparation. The relative activities are calculated by taking the activity (mg. of uric acid oxidised per mg. of preparation) of the original suspension as 1, and the fractions of original activity by taking the mg. of uric acid oxidised per ml. of the original suspension as the basis of comparison with equivalent amounts of the various derived preparations.

The results are best illustrated by the last two columns, from which it appears that the final product is only twice as active as the original, and that the total loss in activity involved in obtaining this product amounts to 96.5%; 56% of the activity of the original product is lost during the process of extraction, and 11% of the activity of the final suspension remains in the residue. Only 35% of the activity of the filtrate is in the acetic acid precipitate, the remainder being partly destroyed by acid and partly remaining in the centrifugates. Finally, the process of drying with alcohol and ether, together with possible mechanical losses associated with incomplete collection of the precipitates, accounts for the loss of 75% of the activity of the wet precipitate.

It follows that purification of the enzyme by extraction with alkaline solutions, followed by precipitation with acetic acid gives eventually products little more active than is the original uricase at the cost of over 96% of its activity.

*Other precipitants.* The action of  $\text{CO}_2$ ,  $\text{CaCl}_2$  and  $(\text{NH}_4)_2\text{SO}_4$  was investigated.  $\text{CO}_2$  at atmospheric pressure did not yield a precipitate and at higher pressures inactivated the enzymes.  $\text{CaCl}_2$  added in quantities equivalent to the  $\text{Na}_2\text{CO}_3$  present yielded a precipitate of  $\text{CaCO}_3$  which had no uricolytic activity. Ammonium sulphate added to half-saturation afforded a precipitate containing 64% of the total activity of the solution.

*Chemical nature of the products.*

The various products obtained by extraction of uricase and precipitation by acetic acid were analysed for N, total P ( $P_T$ ) phosphoprotein-P ( $P_P$ ) and nucleoprotein-P ( $P_N$ ) (eliminated and not eliminated by incubation for 24 hours at 37° with 2% NaOH). 6 g. of kidney powder (Method I; containing N 13.32,  $P_T$  1.1,  $P_P$  0.54,  $P_N$  0.57%) were suspended in 300 ml. of 0.16%  $\text{Na}_2\text{CO}_3$ , and the suspension was filtered after 48 hours at 37°. 0.6% acetic acid was added to the filtrate to attainment of maximum turbidity, the solution was allowed to stand for 3 hours, the clear supernatant fluid was siphoned off, the voluminous precipitate was centrifuged and washed on the centrifuge 3 times with 96% alcohol and 3 times with dry ether, excess of which was removed in a vacuum oven at 30°; 0.38 g. of a white powder remained (N 13.46,  $P_T$  1.76,  $P_P$  0.65,  $P_N$  1.07%). The residue remaining after filtering the first extract was re-extracted, and the extract treated as above, to yield finally a white powder ( $P_T$  1.28,  $P_P$  0.34,  $P_N$  0.94%). The twice-extracted powder was washed with water, dried as above, and analysed ( $P_T$  0.44,  $P_P$  0,  $P_N$  0.44%).

These results indicate that the dissolved uricase is richer in phosphorus, both labile and non-labile, than was the original product, and that the final, inactive residue contains no labile P and less than half of the original nucleoprotein-P. Since it might be thought that inactivation of uricase above  $p_H$  9 is due to elimination of  $P_P$ , determinations of activity and inorganic P were made for a  $p_H$  range of 6.77–10.75, but no regularities were established. The question as to whether a connection exists between phospho- or nucleoprotein and uricase thus remains open.

Ro [1931] stated that trypsin does not inactivate uricase. This question was re-investigated, using Merck's "pancreatin", as follows. 0.5 g. of pancreatin was dissolved in 50 ml. of a 2% extract of uricase, 2 ml. of the solution were immediately added to 10 ml. of 0.11% uric acid solution, and uric acid was determined after 18 hours at 37°; 3.7 mg. were found, as compared with 11.0 mg. initially. The activity of the extract was again determined after incubation at 37° for 24 hours (10.5 mg. of uric acid were found). It follows that the activity of uricase is reduced practically to zero by tryptic digestion, pointing to the protein nature of the active principle.

## SUMMARY.

1. A new method for the preparation of dry uricase has been described.
2. Standard conditions for the determination of the activity of uricolytic extracts are specified; in particular, the importance of keeping the volume of the systems constant and of conducting the reactions in vessels of the same shape and size is emphasized.
3. The reaction is shown to proceed in three stages, involving oxidation in the entire solution by dissolved oxygen, oxidation in the surface zone by atmospheric oxygen and the gradual extension of this zone downwards as a result of diffusion of fresh uric acid from, or of oxygen to, the lower levels.
4. The most active extracts of uricase are obtained by filtering a 2% suspension of uricase in  $\text{Na}_2\text{CO}_3$  solution (of an optimum concentration characteristic for each individual preparation, but of  $p_H$  7.9–8), after standing for 48 hours at room temperature. No advantage is gained by increasing the relative amount of uricase taken for extraction.
5. The activity of the extract represents about 50% of the original activity of the powder; the remainder is lost as a result of the chemical action of the alkaline solution on uricase.

6. The optimum  $p_H$  for the action of dissolved uricase is 8.8.
7. Progressive addition of acetic acid to solutions of uricase leads to the production of an active precipitate, followed by its redispersion.
8. The most active precipitates are obtained by adding acetic acid to  $p_H$  6.99; about one-third of the total nitrogen of the extracts is then in the precipitate and the remainder in the feebly active solution.
9. The enzyme is partly inactivated at  $p_H$  6.99, and totally at  $p_H < 5.8$ .
10. The most active preparation obtained was 8 times as active as the original one; drying with alcohol and ether reduced its activity to twice the original.
11. The N content of the original kidney powder and of the precipitate obtained from the extract is 13.5%; the P content of the precipitate is higher than that of the original powder. Approximately half of the P content of the original powder is eliminated by 2% NaOH, pointing to its phosphoprotein character; the labile P contents of various preparations are very roughly proportional to their activities. Inactivation of uricase by alkaline solutions is not parallel with P elimination.
12. Soluble uricase is inactivated by digestion with pancreatin.
13. Ammonium sulphate precipitates uricase from its solutions with comparatively slight inactivation.  $CO_2$  at atmospheric pressure does not precipitate uricase; under higher pressures it inactivates it. Addition of  $CaCl_2$  in amount equivalent to the  $Na_2CO_3$  content does not precipitate uricase.
14. The view is advanced that uricase is a substance of protein nature.

The authors wish to express their gratitude to Dr D. Assenhajm for performing the phosphorus determinations, and to Prof. St. J. Przyłęcki for his unfailing help and advice.

# CCCXXXII. A MODIFICATION OF YOUNG'S METHOD FOR THE DETERMINATION OF INOSITOL IN ANIMAL TISSUES.

BY RODERIC ALFRED GREGORY.<sup>1</sup>

*From the Department of Physiology and Biochemistry,  
University College, London.*

*(Received October 17th, 1935.)*

SINCE Scherer's isolation of inositol [1850], the attempts to devise satisfactory methods for its determination in animal tissues have been many; but the properties of the substance and the absence until recently of any chemical means of its estimation have rendered the problem difficult. The obstacles encountered necessitate the preliminary isolation of the inositol, and most workers have been obliged to follow this by weighing the isolated product. Young [1934, 1] modified the Fleury-Marque technique for the determination of polyhydroxy-compounds, making it suitable for the estimation of 1-5 mg. of inositol in pure solution with considerable accuracy; a development which made possible for the first time a quantitative study of the various isolation procedures and enabled a method to be produced giving 90% recovery of inositol from tissues [Young, 1934, 2]. This probably represents the highest accuracy to be expected from any method on the same general lines; but in common with all other existing procedures it possesses certain features that render it unsuitable for use in any but the simplest experiments on tissues, especially where only small amounts of material are available.

At the outset of investigations into *post mortem* and other changes occurring in the inositol content of animal tissues, it became evident that little headway would be made until some trustworthy method could be found of determining the inositol contents of amounts of tissues of the order of 5-10 g., and employing also some method of extraction suitable for use in such experiments as the above. The work to be described represents an attempt to meet this need by a modification of the isolation process described by Young [1934, 2] combined with a micro-modification of the same author's method for the determination of inositol in pure solution. An amount of tissue containing not less than 5 mg. of inositol is used (about 3-5 g. of mammalian heart muscle) and the recovery by the process is about 90%.

*Extraction of inositol.* This has been accomplished either by the extraction of the minced tissue with aqueous acetone [Momose, 1916; Needham, 1923, 1, 2; Young, 1934, 2] or by solution of the tissue in alkali, followed by treatment with precipitating agents such as lead acetate [Rosenberger, 1908; Winter, 1934] to remove contaminating substances. Young [1934, 2] also found that treatment with alkali could be made the first stage of a method of determining inositol in tissues.

The use of acetone is inadvisable for two reasons. When small amounts of tissue are to be dealt with, the manipulative difficulties become great, for the

<sup>1</sup> Bayliss-Starling Memorial Scholar (and University Student) in Physiology.

extract must be freed from acetone and ether-extracted before proceeding; but more serious objections to its use are that it is a method of long duration, and that its completeness is open to question unless the sample is extracted at least twice [Young, 1934, 2].

Solution of the tissue in alkali has the important advantages that it is rapid, complete, and easy to use with small amounts of tissue. Winter's [1934] work indicates that the duration of heating in alkali may affect the amount of inositol obtainable from mammalian heart muscle. In the present work the tissues were treated by heating in 10% KOH for the minimum time necessary to bring about their complete breakdown.

Removal of the alkali with a zinc salt has the advantage of removing in the precipitate a considerable amount of unwanted substances. A study was made of the behaviour of inositol in the Somogyi [1930] zinc hydroxide precipitation, using the iodo-mercurate method of determining inositol [Young, 1934, 1]. At least 98% of the inositol was found to be present in the filtrate, and this procedure was therefore adopted as the method of treatment at this stage.

The filtrate after the above process is further clarified with the aid of the West-Peterson reagent [1932], which, as Young [1934, 2] has shown, is very effective for this purpose and permits a 98% recovery of inositol. The filtrate is colourless and odourless and after removal of the mercury is finally subjected to Young's [1934, 2] baryta-alcohol precipitation. Recovery of the inositol at this stage is 96%; and after removal of the barium as sulphate the solution is evaporated to small volume and the inositol crystallised from acetone-ether mixture [Young, 1934, 2].

#### EXPERIMENTAL.

*Extraction.* Into a large pyrex boiling-tube is measured 10% potassium hydroxide from a burette, about 1 ml. per g. of tissue to be used. The tube is heated in a boiling water-bath and the weighed amount of tissue dropped in. The contents of the tube are stirred occasionally with a glass rod, and after heating for the minimum length of time to effect solution (30 min.) the hot solution is washed into a 50 ml. volumetric flask.

*Zinc hydroxide precipitation.* A solution of zinc chloride in dilute hydrochloric acid is used for neutralisation and has the following composition:

Zinc chloride (anhydrous)	...	126 g.	} per litre of solution
Hydrochloric acid (concentrated)		4.5 g.	

1 ml. of 10% potassium hydroxide is neutralised by 1.5 ml. of this solution. It should be checked before use by titration against the alkali, using phenolphthalein as indicator. It has been found preferable to use zinc chloride instead of zinc sulphate in this process: the chloride which passes through to the final product does not affect the determination of the inositol and by its bulk facilitates the collection of the final crystalline material.

The required amount of the above solution is added to the hot solution in the flask with gentle agitation, and a solid mass results. The flask is then heated in the water-bath for a few moments with gentle shaking, when the precipitate becomes lighter and granular in character and the contents of the flask become fluid again. When this has occurred, the flask is cooled under the tap and the contents are made up to volume. After standing a few moments, the contents are filtered on a coarse paper.

*The West-Peterson precipitation.* An aliquot of the above filtrate—30 ml. can usually be obtained—is transferred by pipette to a dry 250 ml. conical flask.

From a pipette are then added slowly with shaking 5 ml. of the acid-mercuric sulphate reagent [West and Peterson, 1932], made by dissolving 27 g. of mercuric sulphate in 100 ml. of 10 % (by weight) sulphuric acid at 5° and separating the solution from any precipitate which forms as room temperature is reached. The mixture is neutralised by the addition of solid barium carbonate (that sold as "pure precip. by soda") until a drop of the solution does not redden blue litmus paper, when the flask is stoppered, shaken for a short time, and filtered on a dry Büchner funnel into a dry flask. The whole of the filtrate is poured into a dry 100 ml. Phillip's beaker and  $H_2S$  passed in the cold without acidification. After filtering on a dry paper into a dry flask, an aliquot of the filtrate is transferred by pipette to a 50 ml. beaker and evaporated on the water-bath to less than 5 ml.

*The baryta-alcohol precipitation.* The solution is transferred to a 30 ml. centrifuge-tube and re-heated in the water-bath. To the hot solution (volume 5 ml.) are now added 2.0 g. of crushed crystalline barium hydroxide, the solution heated for 5 min. with occasional stirring and the tube then removed from the water-bath. Immediately, 20 ml. of absolute ethyl alcohol are added slowly with vigorous stirring, the rod removed and the tube allowed to stand, preferably in the ice-chest, for 2-3 hours.

After the tube has stood for this length of time, it is centrifuged at 3000 r.p.m. for 3 min. and the alcohol poured off. The precipitate is stirred up in 10 ml. of hot water, the sides of the tube being well washed down at the same time, and then from a graduated pipette is added with stirring the required amount of  $N H_2SO_4$  to acidify the solution, a drop of methyl red being added as indicator when the solution is nearly neutralised. Finally a very small amount of norite charcoal is stirred into the solution, this then diluted to 25 ml. with hot water, the rod removed and the tube heated in the water-bath for 45 min. The purpose of the charcoal is to remove the indicator added. Inositol is not adsorbed by charcoal in acid solution, or by barium sulphate under the same conditions, so that no loss occurs. Care must be taken to heat the tube very gently at first, until the remains of the alcohol have been removed, or frothing will occur. When the heating is finished, the tube is centrifuged at 3000 r.p.m. for 5 min. and the solution collected in a 100 ml. beaker. The precipitate is then stirred up in 20 ml. of hot water, re-heated for 30 min., centrifuged and the washing added to the main solution.

*The acetone-ether precipitation.* The solution is concentrated on the water-bath to 5-10 ml., transferred to a 100 ml. flask and re-evaporated to 6 ml. or less. After cooling, 60 ml. of acetone and 30 ml. of ether are added slowly, the sides of the flask scratched with a glass rod to induce crystallisation and the flask stoppered and placed in the cold room for 24-36 hours.

The precipitate which forms is removed by filtration on a sintered glass micro-filter (Schott and Gen., Jena—12G3) or on asbestos on a small Gooch crucible and well washed with acetone and finally with ether. It is then dissolved in hot water, traces of ether being removed from the solution by heating on the water-bath, and then made up to 25 ml. in a volumetric flask. Portions of 5 ml. of this solution are taken for analysis by the micro-modification of the iodo-mercurate method described below.

#### QUANTITATIVE RESULTS.

*Recovery of inositol from pure solution.* In tests of the accuracy of the method, 5 mg. of inositol were subjected to the whole process, being added to 5 ml. of 10 % potassium hydroxide in the boiling-tube, heated, and the "isolation"

proceeded with as above. The following are typical recovery figures obtained in the case of four experiments done at the same time:

Tube	Inositol found mg.	Recovery %
1	4.81	96.2
2	5.22	104.4
3	4.57	91.4
4	5.25	105.0

*Recovery of inositol from heart muscle.* This was tested in the following way, 20 g. of heart muscle were dissolved in 20 ml. of 10 % potassium hydroxide, the solution filtered through a plug of glass wool into a 100 ml. volumetric flask and made up to volume. Of this solution 25 ml. (equivalent to 5 g. of tissue) were transferred by pipette to a 50 ml. volumetric flask and 5 mg. of inositol added. The procedure thereafter was as detailed above. The control was prepared in the same way from the same solution, except that no inositol was added.

Exp. no.	Wt. of tissue taken (A and B) g.	Wt. of inositol added to B mg.	Inositol found		Recovery of added inositol %
			A mg.	B mg.	
1. (Dog's heart)	5	5	7.95	12.45	90
2. (Dog's heart)	5	5	6.80	11.15	87
3. (Sheep's heart)	5	5	4.85	9.61	95
4.     "	5	5	3.37	8.42	101
5.     "	5	5	3.62	7.91	85

The average recovery of added inositol in the above five experiments was 91.6 %.

*The estimation of 0.2-1.0 mg. of inositol in pure solution.*

When amounts of heart muscle of the order of 5 g. are subjected to the isolation process just described, the final solution obtained for estimation will contain about 0.2-1.0 mg. of inositol in 5 ml. In order to estimate amounts of inositol of this order with the requisite accuracy, it is necessary to modify slightly Young's original procedure, which was intended for use with 1-5 mg. of inositol. The modifications consist of heating the solutions in the water-bath in 60 ml. pyrex boiling-tubes, and of using 0.02 *N* iodine and 0.01 *N* sodium thiosulphate solutions for the final titrations instead of the solutions used by Young [1934, 1]. A heating period of 30 min. has been employed, as Young's curves [1934, 1] show the reaction to be practically complete in this time.

*Solutions required.*

Potassium iodo-mercurate solution, made by adding a solution of 288 g. of potassium iodide in water to 108 g. of mercuric chloride in water with shaking, and diluting the solution to 1 litre. The greenish-yellow solution obtained should be filtered if not perfectly clear.

30 % sodium hydroxide solution, stored in a Schellbach burette.

Barium sulphate suspension. 20 g. of the material marketed as "pure for X-ray examinations" suspended in 80 ml. of water. This must be well shaken just before use.

Sulphuric acid. 200 ml. of the pure concentrated acid diluted to 1 litre.

0.02 *N* iodine solution.

0.01 *N* sodium thiosulphate solution.

Starch solution.

Standard inositol solution, prepared from anhydrous inositol, obtained by drying crushed crystalline hydrated inositol at 100-110° to constant weight.

*Procedure.* Into a dry pyrex boiling-tube are pipetted 5 ml. of the solution to be estimated, containing not more than 1.0 mg. of inositol. To this are added 3 ml. of the iodo-mercurate solution from a 10 ml. micro-burette, 4 ml. of the 30 % sodium hydroxide and 2 ml. of the 20 % barium sulphate suspension from a wide-tipped pipette. After mixing the contents of the tube by gentle rotation, its mouth is covered with a glass ball and the tube placed in a boiling water-bath for 30 min., at the end of which time it is removed with as little disturbance of the contents as possible to a bath of cold running water for 5 min. From a burette 8 ml. of the 20 % sulphuric acid are then run slowly into the solution, and the contents mixed by gentle rotation. At the end of a further 5 min., 5 ml. of the 0.02 *N* iodine solution are added from a standard pipette and the contents of the tube well mixed by rotation and by stirring with a glass rod left in the tube. At the end of a further 10 min., with occasional stirring of the solution, this is transferred to a 100 ml. beaker and the excess iodine titrated with 0.01 *N* thiosulphate from a 10 ml. micro-burette (0.05 ml. graduations), using starch solution as the indicator.

The following equivalent titrations were obtained:

mg. of inositol	Equivalent titrations ml. of 0.01 <i>N</i> sodium thiosulphate
0.2	1.70
0.4	3.26
0.6	4.70
0.8	6.27
1.0	7.77

#### SUMMARY.

A modification of Young's method for the determination of inositol in animal tissues is described, suitable for use with amounts of tissue containing 5 mg. or more of inositol. Used in conjunction with a micro-modification of the same author's method for the determination of inositol in pure solution which is also described, the method gives 90 % recovery of inositol from tissues.

The author has pleasure in thanking Dr L. Young for his criticism and advice throughout the work.

# CCCXXXIII. THE EFFECT OF INCOMPLETE DIETS ON THE CONCENTRATION OF ASCORBIC ACID IN THE ORGANS OF THE RAT.

By FREDERICK GOWLAND HOPKINS ASSISTED BY  
BASIL RODERICK SLATER.

WITH AN APPENDIX ON THE IDENTITY OF ASCORBIC ACID  
AND THE REDUCING AGENT OF RAT'S GUT.

By GLENN ALLAN MILLIKAN.

(Received October 30th, 1935.)

## I. EXPERIMENTAL RESULTS.

THE circumstance that certain animals, of which the rat is a typical example, synthesise ascorbic acid in the course of their metabolism raises questions of some scientific interest concerning the nature of its precursors and the seat or seats of its formation in the body. Experience with synthetic diets indicates that its precursors are derived from the main foodstuffs rather than from any minor constituent of the diet, and its constitution suggests of course that these would arise more directly from carbohydrate and perhaps also, less directly, from protein. As a preliminary to any attempt to determine the nature of possible intermediate products it seemed worth while to seek further information concerning its primary origin in the diet. Following Ray [1934], who studied its origin in plant seedlings, Guha and Ghosh [1934] carried out experiments *in vitro* which led them to believe that, as in the seedling, mannose is a preferential precursor for its synthesis in various tissues of the rat (see Section II). Neither mannose nor possible precursors of that sugar were present in the diets of which the effects were studied in the present research.

The paper describes experiments meant to determine the effect of varying the main constituents of the diet upon the concentrations of the vitamin in the liver and small intestine respectively. That it is normally present in the latter is now well known [Hopkins, 1934; Harde and Wolff, 1934; Zilva, 1935; *et al.*]. The estimations were made by the now familiar method of titration with 2:6-dichlorophenolindophenol in acid solution. Details of the method as employed, together with some comments upon certain apparent limitations in its application to animal tissues, will be found in the succeeding section. The animals chiefly used were male albino rats of weights not less than 150 g.

The results of the experiments show that certain fundamental modifications in the food supply, such for instance as the total omission of carbohydrate, or feeding on carbohydrate alone, are almost immediately followed by readjustments in the concentration, and especially in the relative concentrations, of the vitamin in the two organs studied. So rapid are these adjustments that significant changes are observed after the animals have received certain experimental diets for a few days only. By confining their administration for the most part to such brief periods less direct and therefore less significant results, due to the possible effects of abnormal one-sided diets in depressing the processes of general metabolism, have been avoided.

That the concentration of a vitamin in any organ would prove to display some degree of individual differences was to be expected. Even in circumstances apparently uniform variations may well be correlated with other differences in the metabolic condition of animals which are not obvious on inspection. The figures obtained in the following experiments display a scatter which is in some cases fairly wide; but, in general, with respect to the absolute concentrations in the two organs rather than to the relation between these concentrations. It is the latter which is of chief significance to conclusions based upon the results.

It was desirable, in any case, that the numerical data obtained should be submitted to statistical analysis. This has been most kindly carried out by Mr John Wishart of the Cambridge School of Agriculture. The following are the essentials of his report given nearly in his own words.

The most accurate comparisons can be made from the data which concern the ascorbic acid present in the liver and gut of the same animal, for in this comparison other possible sources of disturbance such as age, weight, genetic constitution *etc.* of the rats are standardised. The analysis deals first therefore with consideration of the significance which is attached to the average differences found between the liver and gut concentrations.

The method used for testing the significance of the results was that of "Student" and is expounded by Fisher [1925; 1935]. The assemblies of the organs examined may be treated as "populations" and the problem is to decide for or against an initial assumption (the "null hypothesis" of Fisher) that with respect to the attribute under study the two populations are identical.

If each gut-liver difference is denoted by  $x$ , and there are  $p$  such differences, the ratio ( $t$ ) of the mean difference to its estimated standard error is calculated from the formula

$$t = \bar{x} \div \sqrt{\frac{\sum (x - \bar{x})^2}{p(p-1)}}$$

where  $\bar{x} = \sum (x)/p$ , and  $\sum$  denotes in both cases summation over  $p$  values. By consulting Fisher's table of  $t$ , with  $n$  (number of degrees of freedom) equal to  $p-1$ , we are enabled to approximate to the probability ( $P$ ) that a difference equal to or greater than  $\bar{x}$  should occur in a random sample from a population in which the true difference is zero. Conventionally we may reject this "null hypothesis" concerning the population when  $P$  is less than 0.01. This is expressed by saying that the difference is significant.

The data assembled in the tables which follow, in so far as they are assumed to prove a significant difference between the liver and intestine, are found on analysis fully to justify that assumption. In every such case the probability  $P$  (as above defined) is less than 0.0001. Other references to the results of the analysis appear later.

#### *Effects due to a brief withdrawal of food.*

Before placing the rats upon the experimental diets it was at first thought desirable to withdraw food for a short period in order to eliminate the influence of previous feeding. When however the effects of this abstinence itself were tested, an unexpected result came to light. When animals were kept without food for 48 hours and compared with others on a normal diet, a sharp rise in the concentration of the vitamin in the intestine was found to result from the fast, whilst the hepatic concentration was by then scarcely affected. It was impossible on this account to obtain on such lines basal values for the normal relation between the concentrations in these organs. The values found for rats taken from stock and receiving a mixed diet of oats, wheat grains and bread and milk were

therefore employed as "normals" from which to measure the amounts of change induced by the experimental diets. In such stock animals variation is considerable, but the average values obtained proved to be fully adequate for the purpose of comparison.

In Table I will be found a comparison of the values obtained from animals on the stock diet and those from others which had been deprived of food for 2 days (though never longer). The latter of course were supplied with water.

Table I.

Stock diet			48 hours without food

195	0.29	0.34	205	0.25	0.38
160	0.30	0.32	150	0.31	0.41
135	0.23	0.30	155	0.22	0.33
—	0.26	0.24	—	0.27	0.42
185	0.38	0.36	201	0.25	0.43
—	0.30	0.20	160	0.29	0.43
160	0.27	0.25	—	0.17	0.24
163	0.25	0.22	—	0.31	0.43
—	0.26	0.27	162	0.20	0.31
205	0.27	0.26	—	0.27	0.38
—	—	—	191	0.30	0.42
Average	0.26	0.26	Average	0.27	0.40
Median	0.26	0.25	Median	0.27	0.41

It will be seen that in animals on a complete diet the average concentration in liver and gut is the same, 0.26 mg./g. Analysis of the figures as a whole confirms the fact that there is no difference of significance between them. Equality, or approximate equality, in these two organs seems indeed to be characteristic of normal nutrition. This tends to be the case in spite of individual variations in the absolute concentrations. After the brief abstinence on the other hand in which the average for the liver is scarcely affected, that for the gut rises to 0.40 mg./g.

Inspection of Table I will show that in the case of animals on the normal diet a significant departure from equality in the organs is seen in two only out of eighteen. On the other hand after abstinence the intestinal concentration is significantly higher than that in the liver in all save two out of nineteen. This noteworthy effect of fasting will receive further reference. Its occurrence illustrates the rapidity with which the concentration of ascorbic acid in an organ may be affected by a change in nutritional conditions.

#### *Effects of incomplete diets.*

The diets administered consisted respectively of carbohydrate alone (starch and cane sugar); fat alone (filtered butter and lard); protein ("light white casein") *plus* fat; protein *plus* carbohydrate; fat *plus* carbohydrate. A normal

salt mixture was added to each, but because of the short duration of the experiment no vitamin preparations were supplied. During the periods of administration the carbohydrate diet, and those containing protein and fat and protein and carbohydrate respectively, were well eaten, a normal daily calorie value being consumed. The consumption of the carbohydrate and fat mixture was somewhat less but adequate. The fat was always well eaten at first, though an occasional rat ate sparingly after the third or fourth day. The consumption of a pure protein diet was unsatisfactory, and estimations on this were discontinued.

Although abstinence from food involves the intestinal effect just discussed, experiments in which the diets were given for 3 days after the 2 days' fast proved nevertheless to be informative and were continued. In the tables the results of these appear side by side with data from other experiments in which the diets were fed for 5 days without a previous fast. A few results obtained when the administration was longer will be discussed.

It will be seen from what follows that were the changes found in the hepatic concentration considered alone there would be some grounds for the assumption that the vitamin is made in the liver from precursors derived from carbohydrate. When however the behaviour of the intestine is also considered it becomes clear that this assumption does not by itself cover all the facts.

In Table II will be found the concentrations found in the organs of rats fed upon a mixture of three parts starch and one part cane sugar. The results of 3 days' administration after the 48 hours' fast were identical with those following on 5 to 7 days of the diet without previous fasting. Whilst the concentration in the gut remained normal that in the liver was on the average some 30 % higher. This is not a large variation but the results are consistent, and analysis shows that they are significant. Individual rats showed little departure from the average, especially among the group fed without a fast, and all but two animals out of the nineteen fed show the increase in the liver and a concentration there greater than that in the gut.

concentration on the third day, instead of rising as on the carbohydrate diet, was 0.19 mg./g. only, a figure significantly below the normal. At the same time the intestinal concentration rose sharply. Still confining attention to the liver it should be noted that in rats fed upon the diet for 5 days the concentration in the organ had become normal. That this rise after a preliminary fall is a genuine phenomenon is suggested by the consistency of the data and by the fact that like the earlier fall it is also seen in the case of the other carbohydrate-free diet employed, that containing fat alone (*v. infra*). It seems legitimate to correlate this rise with that adjustment of the liver to a carbohydrate-free diet which is indicated by the early disappearance of the ketosis first induced by such diets. Wigglesworth [1924] showed that in rats on a diet of fat this adjustment occurred about the fifth day. Gemmill and Holmes [1935], moreover, have shown that the glycogen content of the liver of rats fed on butter falls practically to zero on the first day, but gradually rises till on the fourth and fifth days it reaches a level of about 1%. It is justifiable to expect that if ascorbic acid is made from carbohydrate in the liver, the velocity of its formation will increase with increase in the glycogen present up to some normal limit. This limit may be of the low order of the 1% found by Gemmill and Holmes at the fourth or fifth day of a diet of fat. A few estimations of glycogen were made on the livers of rats employed in the experiments just described. Those of two rats which had received the protein *plus* fat diet for 3 days after the 2 days' fast contained 0.31 and 0.43% glycogen respectively (ascorbic acid 0.20 mg./g.); whilst the livers of two others after 5 days on the same diet without the fast contained 1.84 and 1.98% (ascorbic acid 0.26). Within higher ranges of hepatic glycogen, such as were found on diets containing carbohydrate, there was no correlation between it and the vitamin concentrations (see next section). On a carbohydrate-free diet, however, this normal hepatic concentration of the vitamin was not long maintained. Table IIIA gives data for rats kept for 12 days on the protein and fat diet which was consumed in almost normal amounts during that period. By then the average hepatic concentration is seen to have fallen again to the low figure

Table IIIA. *Protein and fat diet, 12 days.*

Weight of rat g.	Ascorbic acid, mg./g.

165	0.18	0.27	190	0.27	0.37
—	0.16	0.34	200	0.24	0.40
Average	0.17	0.30	Average	0.27	0.36

In Table IV are the data for rats on a diet of fat alone. Protein and fat together form, as might be expected, a more satisfactory diet for testing the effect of lack of carbohydrate than one of fat only; but the results of feeding the latter, though fewer animals were employed, confirmed in essentials the most notable effects of the former. The food was less regularly consumed than when the fat was associated either with protein or carbohydrate. It was always eaten freely during 3 days after a fast, but on the fifth day without the preliminary fast an occasional rat was found to have its stomach and intestine empty. Such cases were rejected. It will be seen from Table IV that the group of eight animals fed on fat after the brief fast displayed that low concentration in the liver which characterised the protein *plus* fat diet, namely an average of 0.17 mg./g. only. Again, as on the protein and fat diet, the group of eight fed for 5 days without the fast displayed the secondary rise discussed above.

The results so far considered, showing that a diet of carbohydrate alone induces a relatively high concentration of the vitamin in the liver, whilst the immediate effect of diets lacking carbohydrate is a significant fall, suggest at least what is *a priori* likely, namely, that carbohydrates are the source of its precursors, and further that the liver, alone or in common with other organs, is a seat of its formation.

The behaviour however of the intestinal concentration when these diets are consumed requires full consideration. During the periods when the carbohydrate diet was consumed it remained essentially at the level proper to a mixed dietary and was therefore below the hepatic concentration. In marked contrast

the diet of protein and fat induced a rise in the gut comparable with that which followed the 2 days' abstention. The animals which had consumed this diet for 3 days after the fast showed an intestinal concentration of 0.37 mg./g. This might perhaps have been attributed to a survival from the influence of the fast, but for the fact that animals which had taken the diet for 5 days without a previous fast displayed a similarly high concentration in the gut—0.39 mg./g. (Table III). All the observations have shown, moreover, that the adjustments of vitamin concentrations to the diet are almost immediate. The carbohydrate diet for instance by the third day of its administration after a fast had completely removed the effect of the latter on the gut (Table II).

It is now necessary to consider the results which follow when carbohydrate is fed together with either protein or fat. In Table V are the data for a diet of protein together with a starch-cane sugar mixture. Most of the animals received one part of the former to two of the latter, but it may be remarked that in these binary mixtures even extreme variations in the ratio of the constituents made no difference in the results. This is not surprising. The total amounts of the vitamin produced in the body are small, and if either constituent of the food functions as an efficient precursor very little of it need be present in the mixture.

Table V. *Protein and carbohydrate diet.*

3 days after fast			5 days without fast		
Weight of rat g.	Ascorbic acid mg./g.		Weight of rat g.	Ascorbic acid mg./g.

170	0.19	0.30	230	0.21	0.24
150	0.23	0.26	280	0.25	0.30
Average	0.23	0.29	Average	0.24	0.27
Median	0.22-0.23	0.29	Median	0.24	0.27-0.28

It will be seen from Table V that the diet of protein and carbohydrate induced that approximation to equality in the hepatic and intestinal concentrations which is characteristic of the influence of a complete dietary. This is not so marked in the rats fed for 3 days after the fast, and the data from this group of animals displayed a somewhat wide scatter. Nevertheless the average concentrations come much nearer together than with any of the experimental diets previously discussed. In the ten animals fed for 5 days without previous fasting the average, derived from consistent individual results, was for the liver 0.24 mg./g. and for the intestine 0.27 mg./g. It will be remembered that the average value on a complete diet was 0.26 mg./g. for both.

This same approximation to equality in the concentrations, yielding in each organ an average value of the same order as that found in a normal mixed dietary, was also displayed by rats on a diet of fat and carbohydrate (Table VI). As with protein and fat there was irregularity in the figures when the mixture was taken for 3 days only after a fast, whilst for some reason in the case of the fat and carbohydrate the average figures (from four rats only) though equal were

low. 5 days' feeding, however, undisturbed by the preliminary fast, induced the approximate equality in question at a level close to the normal. Out of sixteen rats placed for this period on carbohydrate in association with either protein or fat only three showed any important departure from this behaviour. Although the approach to equality in the concentrations when the two diets last mentioned were consumed is clear, analysis shows that the rather higher figures for the gut are still significant. It would seem that the intestine adjusts to this binary diet somewhat more readily than the liver.

Table VI. *Fat and carbohydrate diet.*

3 days on diet after 2 days' fast			5 days without fast		
Weight of rat g.	Ascorbic acid mg./g.		Weight of rat g.	Ascorbic acid mg./g.	
	Liver	Gut		Liver	Gut
170	0.21	0.13	170	0.23	0.26
220	0.18	0.19	150	0.19	0.20
190	0.18	0.16	200	0.23	0.23
190	0.19	0.20	210	0.26	0.36
Average	0.19	0.17	220	0.19	0.25
			175	0.19	0.22
			160	0.21	0.27
			225	0.27	0.30
			200	0.26	0.29
			200	0.25	0.28
			170	0.21	0.21
			---	0.30	0.31
			Average	0.23	0.26
			Median	0.23	0.26-0.27

Certain of the experimental results may be here assembled. The following are the average values after 5 days' consumption of the diets, without the preliminary fast. It must not be forgotten that in the case of the carbohydrate-free diets the normal figures given for the liver were preceded by the earlier fall in the concentration.

*With carbohydrate.*

	Liver mg./g.	Intestine mg./g.
Carbohydrate alone	0.32	0.24
Protein and carbohydrate	0.24	0.27
Fat and carbohydrate	0.23	0.26
Normal mixed diet	0.26	0.26

*Without carbohydrate.*

Protein and fat	0.25	0.39
Fat alone	0.28	0.36

It should be emphasised that in these experiments only in animals on the diet of carbohydrate alone was the hepatic concentration ever above normal, or above that of the intestine; and only when carbohydrate was entirely absent did the (more marked) rise in the intestine occur. It would appear that carbohydrate induces approximate equality of concentration in the two organs by inhibiting the rise in the gut which occurs in its absence, while the presence of protein and, apparently, also of fat, inhibits the (less marked) rise in the liver, which the uncontrolled influence of a carbohydrate diet induces.

If the assumption be made that the vitamin is produced in both organs it would appear that when at any time carbohydrate is not available in the diet for production in the liver, synthesis in the gut, presumably from other precursors, proceeds with increased velocity. Such a happening would be rare in the life of the animal, but the capacity of the gut to react in this way would seem to possess physiological interest. It would seem that there must be a mechanism capable of securing some mutual adjustment in the activities of the two organs. The possibilities are further discussed in a later section.

A few animals were kept for longer periods (10 to 12 days) upon each of the diets. It may be said that in general as in the case of the experiment of Table IIIA, the difference in the relative concentrations in liver and gut earlier induced by a diet was still found in each case, but the absolute concentration was in both organs lower.

Determinations on the organs of the guinea-pig were made, but they were few and call for brief reference only. In guinea-pigs normally fed the concentration of ascorbic acid was found to be much lower than in rats, alike in liver and gut, but, as in the latter, approximately equal in both. Four animals yielding closely concordant results gave for the liver an average of 0.13 mg./g., and for the intestine 0.15. It is noteworthy that a 48 hours' fast produced no rise in the latter; rather an appreciable fall. Four animals after fasting showed for the liver an average of 0.13 mg./g., and for the gut one of 0.11. It has been shown by others that the concentration falls in the liver and adrenals during the development of scurvy in the guinea-pig. The intestines of four animals showing marked, but not extreme, symptoms between the fifteenth and twentieth days of a scorbutic diet displayed very low values: 0.02, 0.04, 0.02 and 0.03 mg./g. In these the liver values were 0.07, 0.07, 0.08 and 0.11 respectively.

## II. EXPERIMENTAL DETAILS.

The excellent micro-method of titration with Tillman's reagent described by Birch *et al.* [1933] was closely followed. The acid tissue extracts, of known volume, were run from a standard micro-burette into a measured quantity of the dye; usually 0.05 ml. The solutions of the dye used (approximately 0.01 *M*) were standardised at frequent intervals by titration against pure ascorbic acid. Bezonoff *et al.* [1934] have suggested that the reduction of the dye is a process with a large dilution factor. This is certainly not true within the range of concentrations employed in the experiments here described. Within such a range a solution of ascorbic acid of given strength may be diluted twice or even thrice and then again titrated without any appreciable effects upon the calculated result. Nevertheless the final volume of each extract employed in the experiments was so adjusted to the weight of tissue taken that the titration figures all fell within a relatively small range; in most cases between 0.3 and 0.7 ml. of extract for 0.05 ml. of the reagent.

Several authors have reported general agreement between the results of the titration method and those of biological tests, and it has now become common to accept the former without question. This however might seem unjustifiable in the case of material such as the tissues of gut which have not been tested biologically.

It proved impossible to administer intestinal tissues or aqueous extracts made from them to guinea-pigs for adequate periods. Attempts to do so have given indications of protection, but the animals have nearly always died prematurely and adequate biological proof that the gut contained ascorbic acid in concentration corresponding with the titration results was not obtained.

On the other hand it seems that evidence on the following lines is in itself sufficient to show that when applied to intestinal extracts the figures obtained by titration represent ascorbic acid and that substance alone.

In acid solutions the reduction of Tillmann's reagent by ascorbic acid proceeds with a velocity which is out of all proportion greater than reduction by any other substance (cysteine, glutathione, phenols *etc.*) known to react with the dye. It is easy on the other hand to show by relatively simple means that if the amount of the vitamin in a given intestinal extract be assumed to correspond with the titration figure, and if a solution of pure ascorbic acid be prepared of equivalent strength and similar  $p_H$ , the extract and the solution will reduce a given amount of dye with a velocity which to all appearances is the same. To give precision to such evidence Dr G. A. Millikan kindly undertook to determine quantitatively the rate of reduction by previously titrated extracts, comparing it with that of reduction by pure ascorbic acid and cysteine solutions of equivalent strength. He has provided an account of his experiments which should be of interest to other workers (see Appendix, p. 2817).

Having regard to very great differences in the velocity of reduction by ascorbic acid and cysteine respectively, and to the circumstance that, roughly observed, the reduction of the dye by *e.g.* phenolic substances, while slow, differs in velocity from one case to another, the identity of the velocity constants for pure ascorbic acid and the reductant from the intestine seems strong evidence in favour of the titration method.

While this applies to the gut and, it would seem, almost certainly to most other organs, it is well to note that there may be exceptions. The kidney, for instance, to judge at least from experience gained in the course of this research, is an organ which offers difficulties. In titrating acid extracts of the gut and liver (when the organs have been removed from the body without undue delay) there is, as in the case of solutions of pure ascorbic acid, no difficulty in deciding upon the end-point, and different observers readily agree when determining it. Moreover, it is significant that in the case of extracts from these organs the actual rate of titration may be widely varied without affecting the final result. It is otherwise with extracts from the kidney. If in the case of this organ an extract is first titrated quickly and then more slowly, it is found that the results are by no means the same. If indeed (the extract being in the burette) a pause is made between each successive addition so that the titration occupies a minute or longer, decoloration of the dye may occur when no more than, say, half of the extract required in the quick titration has been added. Slowly reducing substances in exceptional amounts are usually if not always present in kidney extracts. It is known to histologists and others that the kidney is exceptional in the rapidity with which it undergoes change after removal from the body. Catheptic activity for example is exceptionally great in this organ. Whether autolytic products account for the difficulty in titration is uncertain, though likely. It occurs, however, when there has been no more than ordinary delay in the treatment of the organ after its removal. It is sure that, even in the case of the liver or intestine, long standing even at room temperature before extraction makes titration more difficult in the above sense. Needless to say this occurs more rapidly on incubation of the organs. Guha and Ghosh [1934] have described experiments to show that various organs can produce ascorbic acid from mannose but not from glucose when incubated with these *in vitro*. The titration values rise considerably however when tissues are incubated alone. It would seem therefore that, in order to make the evidence on these lines for a real increase of the vitamin of any value control samples must in any case be incubated side by

side with the experimental samples while the final titrations must be fast and very uniform in rate. It is probable that the above authors are aware of this difficulty and have allowed for it. The circumstance that they report negative results with some sugars seems proof of this.

In the greater number of the experiments male albino rats were used, of weight varying from about 150 to 200 g. Quite young animals (50 g. or under) tend to show higher absolute values for the vitamin concentrations than those more mature, so that in testing the effect of a given dietary they are not strictly comparable with the latter. It was thought that females might show greater variation than males in the normal amount of vitamin so, perhaps without sufficient reason, they were infrequently used.

The animals were killed instantaneously by stunning, and the throat was immediately severed to allow free drainage of blood. The organs were removed as quickly as possible and ground up under trichloroacetic acid in the presence of a little sand. The final volume was in each case made proportionate to the weight of tissue taken and the extracts as titrated contained approximately 2.5% trichloroacetic acid.

It is perhaps desirable to describe here the preliminary treatment of the gut before extraction. It was uniform in all experiments. The small intestine was cut at its pyloric and caecal ends and removed intact; the mesentery being peeled off during the gradual removal of the gut from the abdomen. Its contents were washed out by a stream of water at 37°, and the residual water removed by "milking" the gut with moistened fingers. It was then gently squeezed between filter-papers. To make sure that such treatment did not leave a variable amount of adherent moisture a portion of the intestine was in a large number of cases reserved for the determination of water content. The variations were small; the departures from the average of 78.2% total solid matter being such as would affect the figures obtained for ascorbic acid by at most a unit in the second decimal place. In the case of the liver the whole organ or a suitable proportion of it was weighed and ground up at once under trichloroacetic acid. The metabolic condition of the liver—its variable content of water, glycogen or fat—must of course indirectly affect to some degree the observed concentration of the ascorbic acid. It seems clear, however, that variations in these were not of sufficient magnitude or, alternatively, not of the right kind, to diminish the significance of the variations displayed by the vitamin concentration.

In a proportion of cases a sufficient amount of the liver was reserved for estimations of the glycogen by the method of Good, Kramer and Somogyi, and in some others the total nitrogen was estimated by Kjeldahl. In the case of the groups compared when one was fed carbohydrate only and the other protein and fat (Tables II and III) the livers of two rats from the former group contained 5.64 and 3.67% glycogen respectively, whilst those of two from the latter group contained only 0.31 and 0.43%. This difference would of course somewhat disturb a comparison of the true cytoplasmic concentrations of ascorbic acid, but it is clear that any attempt to correct for this would somewhat increase and not diminish that difference between the groups in question which has been claimed as significant. The differences in glycogen content of livers from sample animals from groups otherwise fed and compared were much less than this. The total nitrogen of the livers of animals fed on carbohydrate alone showed an average, based on twelve cases, of 2.84% from which individual departures were remarkably small. The average in the livers of those fed protein and fat was 3.30, again with small departures from this mean. If the total nitrogen be taken as a measure of the cytoplasmic contents of the livers, this again shows that the difference between

the true concentrations of ascorbic acid in the two groups in question (the significant point) is somewhat greater than the figures indicate. The nitrogen figures found for animals on diets of protein or fat together with carbohydrate have differed but little from those of animals on complete synthetic dietaries.

### III. DISCUSSION.

The experimental results reported and briefly discussed in the first section show that when rats are placed for short periods on certain dietaries (incomplete in the sense that one or more of the three main organic foodstuffs was lacking) the concentration of ascorbic acid in the two organs specially studied, namely the liver and the small intestine, may vary with the nature of such diets. The absolute concentrations may rise or fall with a change in the nature of the diet, and the relation between the concentration in one organ and that in the other may come to show wide differences. Any such adjustment to a change in the diet is always rapid.

The essential experimental results can be summarised in the following statements. The numerical data upon which the statements depend have been shown by statistical analysis to possess the significance here claimed for them (see p. 2804).

1. During the consumption of a normal mixed diet the average concentration of ascorbic acid was found to be the same in both organs, namely 0.26 mg./g.

2. A fast of only 48 hours was found to produce a rise in the intestinal concentration which reached an average value of 0.40 mg./g. The concentration in the liver was by then scarcely affected (Table I).

3. On a diet containing carbohydrate alone, whether administered for 3 days after a fast of 2 days, or for 5 days without the previous fast, the hepatic concentration rose to an average of 0.33 mg./g., whilst that in the gut remained normal (Table II). The increase in the liver, though not large, is outside the limits of experimental error and is statistically significant.

4. When on the other hand a diet containing protein and fat without carbohydrate was consumed for 3 days after a fast, the concentration in the liver fell to the low average value of 0.19 mg./g., while the intestinal concentration rose to 0.37, this high value being also displayed after 5 days of the diet without the fast (Table III). On a diet of fat alone the results were essentially the same (Table IV).

The immediate fall in the liver induced by carbohydrate-free diets was, it is true, followed by a return to normal on the fifth day of feeding. It is almost sure, however, that this is correlated with the known circumstance that the livers of rats adjust to a carbohydrate-free diet on about the fifth day of its consumption. The hepatic glycogen which in rats fed upon fat alone at first falls to near zero, rises by then to concentrations round 1% [Gemmill and Holmes, 1935], and this is associated with the disappearance on or about the same day of the ketosis first produced by a fat diet [Wigglesworth, 1924]. If therefore the precursors of ascorbic acid in the liver arise from carbohydrate it is clear that this becomes more available for the purpose at about the fifth day of a diet of fat or of protein and fat.

5. Whilst the hepatic concentration was raised by feeding carbohydrate exclusively, and the intestinal concentration was raised when diets without carbohydrate were consumed, it was next found that a diet of protein and carbohydrate produces approximate equality of concentration in the two organs at a figure corresponding to that found in rats on a normal mixed diet (Table V). A diet of fat and carbohydrate produced the same situation (Table VI).

If the behaviour of the vitamin in the liver were considered alone, showing the rise above the normal concentration, and above that in the gut, after a diet containing only carbohydrate, and on the other hand a rapid fall on the two carbohydrate-free diets, there would be sufficient evidence to support the natural expectation that carbohydrates supply precursors for ascorbic acid, and, further, the suggestion that the liver, alone or in common with other organs, is the seat of the formation. The behaviour in the intestine however clearly raises other issues.

The intestinal concentration seems to be more flexible than the hepatic, and the notable rise in the former displayed by all the animals when placed on carbohydrate-free diets, is the most striking effect which the experiments under discussion have revealed. It seems fully justifiable to believe that the intestinal rise from 0.26 to 0.40 mg./g. found to follow a brief fast is itself due to a specific effect of failure in the carbohydrate supply, since it was entirely prevented by the consumption of a starch-sugar mixture alone, whereas a rise of a magnitude similar to that induced by the fast occurred rapidly on the diets which were carbohydrate-free. Data from nearly ninety rats deprived of carbohydrate were therefore recorded during the experiments, and the high intestinal concentration was displayed by every animal save four or five. The gut of no single rat out of nineteen on a carbohydrate diet displayed this behaviour, and among the same number of animals upon a normal diet yielding the average of 0.26 the gut of only one was found to depart so far from the average as to approximate to the high concentration in question.

The experimental result which has finally to be taken into consideration is the maintenance by diets of protein and carbohydrate, or fat and carbohydrate, of approximately equal concentrations in the two organs at a value which is that maintained by a normal mixed dietary.

In considering the results as a whole it seems justifiable to dismiss the suggestion that the organs studied represent seats of storage for the vitamin rather than seats of formation. It is very unlikely that changes in diet would promptly affect the relation between the concentration in the liver and that in the intestine if each organ was receiving its supply from another source.

If, as seems certain, ascorbic acid is produced in both of the organs studied, the results of the experiments almost compel the assumption that the intestine can call upon a source yielding primary precursors for synthesis which is less readily available for the liver. They suggest moreover that there must be some mechanism through which a mutual adjustment in the productive activities of these organs is established. With the diminution of production in the liver owing to a failure in the carbohydrate supply, the rate of synthesis in the intestine is—as it were vicariously—increased.

It may be useful at this point to recall the following results. On a diet of carbohydrate alone the average concentration in the gut was 0.24 mg./g., on carbohydrate with protein 0.27, and on carbohydrate with fat 0.26; that is to say, on all diets containing carbohydrate when consumed for 5 days the concentration was essentially the same, being that found on a normal mixed dietary and, incidentally, essentially also the same as that in the liver when protein or fat was fed with carbohydrate. It seems reasonable to suppose therefore that so long as carbohydrate is supplied in the food it is the preferential source of the vitamin precursors for both organs alike. On the other hand with a protein and fat diet the average intestinal concentration was 0.39 mg./g., with fat alone 0.36 and, after a fast, 0.40. Thus in all cases where no carbohydrate was supplied, the gut concentration was essentially the same at an average figure some 50 % higher than that so consistently found when carbohydrate was available in the food.

It would seem clear therefore that in the rat the cells of the intestinal epithelium—unlike the hepatic cells, or much more readily than they—can, when deprived of carbohydrate, turn to protein or fat as a primary source of precursors for the synthesis of ascorbic acid. Owing to the constitution of the vitamin it is even then likely that carbohydrate formation is an intermediate stage, and that therefore the primary source is most probably protein. It is true that the intestinal rise occurs on a diet of fat alone, no less than on one of protein and fat, and in the case of that temporary adjustment in the liver to a carbohydrate-free diet earlier discussed, it is likely, to judge from the experiments of Gemmill and Holmes, that an adequate amount of carbohydrate had in the case of that organ been derived from fat. Evidence that carbohydrate can be formed in the body from fat seems to be growing, but it does not suggest its formation in the intestine. It must in any case be a process of low velocity compared with that of the formation of glucose from certain amino-acids [*cf.* Csonka, 1915; Janney, 1915]. It is, on the other hand, not difficult to believe that failure in a carbohydrate supply involves some increase of protein breakdown in the intestinal epithelium, and that precursors of ascorbic acid may thus undergo a local endogenous increase. This seems at least a reasonable hypothesis on which to explain the well established behaviour of the gut concentration whenever there is failure in a carbohydrate supply. It is well to remember that the search for the precursors of a vitamin produced in the body differs from most studies of intermediary metabolism in that the amounts of materials necessarily involved are so small.

Complete absence of carbohydrate from its food would be a rare event in the life of the animal, but the capacity of the gut to increase its production in circumstances which lead to a decrease in the liver, and possibly in other organs, is a case of physiological adjustment not without interest. Whether other organs which may function in the production of ascorbic acid resemble the liver or the intestine in their reaction to dietetic factors was not adequately investigated in this research.

In the case of the guinea-pig, which is of course unable to produce ascorbic acid endogenously, a few experiments showed that any increased intestinal concentration due for instance to a brief fast was entirely absent. In scorbutic animals the concentration in the intestine was found to be very low (average 0.03 mg./g.).

#### SUMMARY.

In rats consuming a normal mixed dietary the average concentration of ascorbic acid in the liver and in the small intestine is the same.

When carbohydrate forms the sole organic constituent of the food consumed, the hepatic concentration immediately rises, becoming higher than that in the intestine.

On the other hand, when carbohydrates are absent from the food the concentration in the liver rapidly falls, while that in the intestine rises to a high value.

Possible explanations of these readjustments in the concentrations are discussed.

## APPENDIX.

## THE IDENTITY OF ASCORBIC ACID AND THE REDUCING AGENT OF RAT'S GUT.

By GLENN ALLAN MILLIKAN.

The present experiments, undertaken at the suggestion of Sir F. G. Hopkins, were designed to provide a rather critical test for the identity of the reducing agent found in trichloroacetic acid extracts of rat's gut and ascorbic acid. They consisted in measuring comparatively the rate of reduction of Tillman's reagent (2:6-dichlorophenolindophenol) by these two substances, as well as by cysteine. Good agreement was found between the gut extract and ascorbic acid. Taken in conjunction with the widely divergent cysteine value, the result provides strong evidence for the suspected identity.

Since the reactions were too fast to follow by ordinary procedures, the continuous flow method introduced by Hartridge and Roughton [1923], and developed for non-haemoglobin reactions by Millikan, was used. The solutions were prepared by Hopkins, using the extraction method described by him in the accompanying paper. A solution of Tillman's reagent was made up to a concentration suitable for the kinetic measurements (usually 0.2 mg. per ml.), and the extract was standardised against it by titration, its concentration being adjusted until it was 20–40 % greater than that of the dye, the solution containing 2.5 % trichloroacetic acid. An exactly equivalent solution of ascorbic acid, also in 2.5 % trichloroacetic acid, was then prepared, its concentration being checked by titration against the same dye. The solutions were placed at once in the storage reservoirs of the apparatus, which was arranged so that one could quickly change from the gut extract to the ascorbic acid as the reducing agent (Fig. 1).

Fig. 1. Simplified diagram of the apparatus.

In measuring the velocity of reduction, the two reacting fluids were drawn into their respective syringes from the storage vessels, and were then driven by an electric motor at a known constant rate through the two converging tubes to

the mixing chamber, whence they issued as a single thoroughly-mixed stream down the observation tube. The extent of the reaction as measured by the decoloration was observed at different points along the tube, the colorimeter being a simple photo-electric one using colour filters and a rectifier type of cell [Millikan, 1933]. A 4 volt, 8 watt lamp was used as light source, the two filters being Wratten No. 29, red, and No. 56, green. The device is suitable for measuring reaction times from about 1/1000 sec. to 1/2 sec., and the concentrations of the reactants were so chosen that the rates fell into this range.

The results of a typical experiment are shown in Fig. 2. It is seen that over the very critical early portion of the curve—in fact up to 60 % completion of the reaction—the two solutions reduce with identical velocities. At the end of the

Fig. 2. Rate of reduction of Tillman's reagent.

reaction, the gut extract was sometimes a little slower in its action. It is not thought, however, that this final spread between the two curves is significant, because it is always small, and because it only shows itself near the end, when the reaction is proceeding slowly, and where one might expect it to be more susceptible to inhibiting effects of foreign substances in the gut extract. No attempt was made to purify the extract other than by filtering through paper, and slight effects (due perhaps to the slow adsorption of the dye on colloidal molecules in the extract solution) are almost to be expected. The striking fact, on the contrary, is that the two agree as well as they do, when it is considered that large changes in the rate are brought about by small alterations in the concentrations of the reactants and in the  $p_H$  of the solutions, as found from the control tests described below.

In contrast to these small differences, the rate of reduction of Tillman's reagent by cysteine is about 350 times as slow as that by ascorbic acid when measured under the same conditions. Thus, in the first one-tenth of a second, ascorbic acid has more than half completed reduction of the dye, while cysteine has only reduced about one-thousandth of it. A few orienting experiments of Hopkins indicate

that glutathione and materials precipitated from tissue extracts by mercuric acetate act even more slowly than does cysteine so that of these possible claimants ascorbic acid is the only one which is even in the running.

*Controls. 1. Decay with time.* Since the reducing power of solutions of ascorbic acid is known to fall off in the course of time, it was thought desirable to sandwich the gut extract readings between two sets of observations on the ascorbic acid (hollow circles and dots respectively in Fig. 2). These showed that there was no decay in the rate during this time.

*2. Effect of  $p_H$ .* The rate of the reaction is very sensitive to alterations in the  $p_H$  of the solution, becoming progressively slower as the alkalinity is increased, until at neutrality the rate is about 1/40 of that in the trichloroacetic solutions (which have a  $p_H$  of about 2). This explains the necessity for using the same solvent for the ascorbic acid and for the gut extract in the kinetic experiments.

### *The bimolecular order of the reaction.*

A tenfold variation in the concentration of the ascorbic acid, and a twofold variation in that of the dye left the bimolecular velocity constant unaffected:

Conc. of ascorbic millimols/litre	Conc. of dye millimols/litre	Bimolecular velocity constant, $K$ 1/millimols $\times$ sec.
0.073	0.057	$30 \pm 5$
0.136	0.112	$30 \pm 5$
0.71	0.125	$34 \pm 5$

Temp.  $20^\circ$ . (An experiment at about  $22^\circ$  gave a value for  $K$  of  $39 \pm 2$ , indicating a high temperature coefficient for the reaction, but the data are insufficient for its calculation.)

If the reaction were of either higher or lower order than the second, the value of  $K$  would have varied widely. The agreement obtained is therefore strong evidence that the reaction actually proceeds according to the expression:

# CCCXXXIV. A SIMPLE PROCESS FOR ESTIMATING AMINO- OR OTHER BASIC GROUPS IN AMINO-ACIDS *ETC.*: THE "GLACIAL ACETIC ACID" METHOD.

By LESLIE JULIUS HARRIS.

*From the Nutritional Laboratory, University of Cambridge and Medical Research Council.*

(Received October 31st, 1935.)

A STUDY of the titration curves of the amino-acids [Harris, 1923, 1] shows that their amino-groups are quantitatively converted into their hydrochlorides (or similar acid salt) when the  $p_{\text{H}}$  is reduced to a value approaching 0.5 to 0 (for titration constants of certain individual amino-acids, *c.f.* Harris [1923, 2, 3; 1929, 1]; Birch and Harris [1930]). In other words, provided that one starts with the free amino-acid and titrates it to a sufficiently acid end-point the amount of acid entering into combination with it is then stoichiometrically equal to its amino- or other basic groups.

(It does not affect the argument whether the original ampholyte was of the zwitterion or non-zwitterion type—*i.e.* whether any of its acid or basic groups were present in the non-ionised or fully ionised, internal salt, form. For, at the conclusion of the titration all the basic groups are present as hydrochloride, and at the beginning there was no combined HCl.)<sup>1</sup>

It becomes apparent at once therefore that a simple method for estimating the amino-groups is to measure the amount of acid needed to titrate them to a highly acid end-point ( $p_{\text{H}}$  0 to 0.5). There is only one disadvantage to this procedure from a practical standpoint, that is that the "blank correction" is very large. That is to say, in addition to the HCl which is needed to bring the amino-acid itself to the desired  $p_{\text{H}}$ , a considerable further amount will be needed to bring the solvent (water) to the same highly acid reaction. This is shown in

<sup>1</sup> The equation for an acid ampholyte (*e.g.* glutamic or aspartic acid) is

for a neutral ampholyte (*e.g.* glycine *etc.*),

and for a basic ampholyte (*e.g.* lysine *etc.*),

Fig. 1, from which it will be seen also that the magnitude of the blank correction is increased (and the accuracy of the titration is accordingly diminished) in proportion to the final dilution of the solution.

Fig. 1. Titration curve of glycine with HCl: ideal, and at dilutions of  $N$ ,  $0.1 N$  and  $0.01 N$ . At any  $p_H$  level the difference between the ideal curve and the curves  $A$ ,  $B$  or  $C$  represents the blank correction at the given dilution. (In the example represented, the total volume is imagined as kept constant at the dilution shown, for every reading on the curve.)

In short, when the titration is thus carried out in aqueous solution there is no steep change in  $p_H$  at the end of the titration. Hence it is impossible to obtain a sufficiently sharp colour change in an indicator to mark a sudden end-point to the titration. As was pointed out in the original paper in this series [Harris, 1923, 1] the difficulty may be obviated in two ways. Either the amino-acid may be titrated in very concentrated solution, in which case the blank is relatively small (if the measurements of  $p_H$  are made electrometrically, the blank correction may be worked out theoretically with some degree of accuracy). A more simple procedure, however, is to use in place of the water some alternative solvent which needs only a negligible "blank" to bring it to the required  $p_H$  end-point of 0.5 to 0. Then the titration is reduced to the easiest of all chemical methods—*viz.* the simple addition of titrant from a burette until, with the last drop, the indicator abruptly changes its colour.

A number of suitable solvents was tried and eventually glacial acetic acid was chosen as the most satisfactory. It has been known for many years as a convenient solvent for most bases and has already been utilised by Hall and Conant [1927; see also Conant and Hall, 1927; Hall and Werner, 1928] for electrometric measurements on bases in "super-acid" solutions. A suitable indicator was found in brilliant cresyl blue (obtainable from The British Drug

Houses, Ltd.), which is soluble in glacial acetic acid and undergoes a clear colour change from blue to yellow at a  $p_K$  value near 0 (yellow with increasing acidity: the  $p_K$  value of the indicator in water is given as 1 to  $-0.2$ ).

Routine tests were accordingly carried out with all the better known amino-acids, and it was found that results of about 99 % accuracy could be obtained without difficulty. This work was concluded in 1929, and a summary of the conclusions was given in that year, when the method was applied to glutathione to determine the number of basic groups and the combining weight [Harris, 1929, 2]. Pressure of other work has since delayed the presentation of the extended figures on the complete series of amino-acids. It is felt however that the method is such a convenient one and capable of such wide application that at the suggestion of other workers the full working directions are now being published.

#### EXPERIMENTAL.

*Preparation of specimen.* The principal use of the method in the writer's experience has been to estimate the basic groups in isolated preparations in the solid form, more particularly as an aid in the characterisation of unknown substances. It is suitable for applying directly to a specimen of the free (isoelectric) amino-acid, ampholyte, base *etc.*, rather than to a sodium salt or hydrochloride *etc.* If such added acid or alkali is present it should be neutralised with an equivalent amount of alkali or acid before the titration is begun. It is always preferable and simpler, however, to carry out the estimation on the free substance itself whenever this is available. It is essential that the specimen to be titrated should be dry. If estimations are required on a solution, therefore, an aliquot part of it should be taken and the solvent evaporated.

*Standard acid solution.* As a titrant possessing more strongly marked acid properties than HCl, and readily miscible with glacial acetic acid, perchloric acid has been used throughout. A stock solution is prepared for the writer by The British Drug Houses at 1.0 *N* dilution,<sup>1</sup> and this is then further diluted with glacial acetic acid to the strength desired for each titration, generally 0.1 *N*.

*Standard glycine for back-titration.* It is convenient to have a solution of standard base for purposes of back-titration. I have found that at the very acid reactions used, a solution of glycine in glacial acetic acid serves the purpose very well. To prepare a 0.1 *N* solution, dissolve 0.7505 g. of glycine in glacial acetic acid, bringing the final volume to 100 ml.: the glycine may take a few hours to go entirely into solution.

*Indicator solution.* A suitable final dilution for the indicator, *i.e.* at the end of the titration, is from about 0.0015 to 0.003 %. Stock solutions of 0.01 or 0.1 % should be made up in glacial acetic acid.

*Directions for rapid routine procedure—semi-micro-scale.* In carrying out a titration, an amount of the dry specimen is weighed out (*e.g.* about 15 mg. in the case of glycine) which would yield about 2 ml. of 0.1 *N* solution. This is placed in a small stoppered weighing bottle (*e.g.* 10 ml. size), and a slight excess of the standard 0.1 *N* perchloric acid solution added from a burette reading to 0.01 or 0.02 ml. (The advantage of adding excess of acid in this way is that the specimen then goes more readily into complete solution.) The stopper is replaced

<sup>1</sup> To prepare *N* perchloric acid in 100 % acetic acid, the following procedure, described by Hall and Werner [1928], may be followed: Add 8 *N* aqueous perchloric acid to the theoretical quantity of chilled acetic anhydride and dilute with glacial acetic acid to *N*. It is important to have no excess of acetic anhydride or water, which can be prevented by adding a few drops of  $H_2O$  or  $As_2O_3$ , as necessary, until no further temperature rise is shown on a thermometer.

to keep the solution free from moisture, and as soon as the specimen is all dissolved a suitable amount of the indicator solution is added (*e.g.* 1 ml. of 0.01 % solution of brilliant cresyl blue in dry glacial acetic acid).<sup>1</sup> The end-point is then determined by back-titration with 0.1 *N* glycine, a second burette also reading to 0.01 ml. being used. The difference between the acid titre and the back titre with glycine gives the amount of amino-nitrogen, or other basic group, present. For greater accuracy the result should be corrected for a small blank correction. The blank correction is the amount of standard perchloric acid solution needed to bring the solvent and indicator alone, in the absence of the solute, to the same end-point colour change, the volume of solvent being the same as at the end of the actual titration. (Under the conditions described the blank correction is no more than about 1 % of the titre; or less if a more precise technique is adopted; see below.)

*Results obtained by the routine, semi-micro-method.* In Table I are assembled the results obtained on most of the better known amino-acids, and a number of polypeptides, bases and other substances.

It will be seen that without special precautions having been taken results of about 99 % accuracy were readily obtained.

Table I. *Routine determinations of basic groups in amino-acids etc.*

\* *a* = Volume of 0.1 *N* perchloric acid added, ml.; *b* = Volume of 0.1 *N* glycine needed in back-titration, ml.; *c* = Blank correction for given final volume, as ml. of 0.1 *N* perchloric acid.

† Several specimens of arginine examined titrated as though containing varying amounts of water, intermediate between anhydrous, monohydrate or dihydrate.

‡ Results for this specimen agree better with theoretical values calculated for  $\frac{1}{2}$ H<sub>2</sub>O, rather than 1H<sub>2</sub>O or anhydrous.

§ Amounts taken are expressed here in terms of ml. of 0.1 *N* solution.

|| mg.

#### Additional comments on technique.

*Duplicate determinations of end-point.* To check the titration reading, whenever desired, a series of further additions of standard acid may be made from the burette and the end-point again determined after each addition, by further

back-titration with standard glycine (see, *e.g.* sarcosine, No. 26, Table I). (If the volume is increased considerably in this way, the "blank" must be corrected in proportion.)

*Colour standards.* Where great precision is desired, the colour of the indicator at the end-point may be matched between that of control solutions accurately adjusted to two or more given intermediate tints.

*Direct titration of bases.* Bases in general dissolve more readily than do ampholytes, and therefore the estimation can be completed quickly by direct titration with perchloric acid to a straightforward end-point: little is gained in such cases by back-titration with standard base (see, *e.g.* creatinine, Nos. 32-35, Table I).

*Exclusion of moisture.* It is essential to keep the burettes and bottles containing the stock solutions well stoppered to prevent access of moisture, which interferes with the sharpness of the end-point. An unsatisfactory reading can in fact generally be attributed to the presence of moisture. The standard glycine and *N* perchloric acid appear to keep almost indefinitely, and the dark brown colour of the latter must not be taken to indicate any deterioration of strength. (A specimen of the *N* perchloric acid was examined after the lapse of 6½ years and found to have retained its strength unimpaired.)

*Management of burette.* Experience indicates that most accurate results are obtained when the tip of the burette is kept above the surface of the liquid which is being titrated, in order to prevent diffusion. As each fresh reading from the burette is made, the tip is touched on the side of the vessel just above the resting surface of the liquid which is being titrated, so as to remove quantitatively the fraction of a drop expelled. Glacial acetic acid has this advantage as a solvent, that its surface-tension is relatively low and hence it does not "cling" to the walls of the burette or other vessel.

*Alternative titrants and indicators.* In a series of determinations, aniline in glacial acetic acid was used as an alternative standard base for back-titration. It was found to have the disadvantage of keeping less well than glycine. On the other hand because of its greater solubility it may be made up at greater strengths, and is therefore useful when micro-titrations with *N* reagents are desired (see Table V).

Various other indicators were tried also as alternatives to brilliant cresyl blue, including dianisylacetone and triphenylcarbinol. It was thought that, theoretically, the use of an indicator with a  $p_K$  value even lower than that of brilliant cresyl blue might sometimes be useful: but in practice such excellent results were obtained with the latter that there seemed little or no practical advantage in replacing it.

*Theoretical considerations.* At the  $p_H$  value approaching 0, taken as end-point in this method, all the amino-acids, as well as polypeptides and proteins, have their basic groups ionised as acid salts, whilst the ionisation of the acid (carboxyl or hydroxyl *etc.*) groups is repressed. Hence the end-point is adequate for estimation of basic groups without any danger of interference from the acid groups. Or, looking at the question from another angle, we may say that in glacial acetic acid the ampholyte is quantitatively converted from zwitterion into its basic form.

In general, it may be claimed that with the indicator chosen the method is suitable for the estimation of the weakest bases ( $K_B > 10^{-12}$ ) even in the presence of relatively "strong" organic acids ( $K_A < 10^{-2}$ ). (The figures given in parenthesis are applicable when the amounts of acid present are not grossly in excess: if very large excess of relatively strong acid is present, or the base to be estimated

is very weak, it is always possible to increase the accuracy of the titration by a still further decrease in the  $p_H$  value of the end-point.)

*Inorganic salts and mixtures.* The presence of neutral inorganic salts (*e.g.* NaCl) does not appear to affect appreciably the accuracy of the method (see, *e.g.* Nos. 50 and 51, Table I). Mixtures of amino-acids and bases are estimated as correctly as are single substances (see, *e.g.* Nos. 47 and 49, Table I).

*Application to proteins.* An effort was made to apply the principle of the method to the estimation of basic groups in proteins. Most of the experiments were carried out with powdered gelatin. The principal difficulties to be overcome were (1) to bring the protein into solution or, at any rate, to get it to react reasonably rapidly with the acid reagent; and (2) to get the protein into a "dry" state. Following a suggestion by Dr David Greenberg, formic acid was also tried as a solvent for proteins; but its use did not entirely obviate the objections referred to. As the technique for proteins needs modifying considerably from that described here, details may be well postponed for a later paper.

#### *Sensitiveness of method.*

To determine the sharpness of the end-point the following experiments (Table II) were carried out with 0.1 *N* glycine, and with *N* aniline, each titrated against *N* perchloric acid.

Table II. *Determination of sensitivity of method.*

Exp. no.	Solution taken for estimation	Amount of brilliant cresyl blue indicator added	Amounts of titrants added	Result
1	5.0 ml. of 0.1 <i>N</i> glycine	0.05 ml. of 0.1% solution	Added 0.51 ml. of <i>N</i> perchloric acid. Then back-titrated with 0.1 <i>N</i> glycine	Colour change was sharp to <0.01 ml. of 0.1 <i>N</i> glycine in back-titration
2	1.0 ml. of <i>N</i> perchloric acid	0.2 ml. of 0.1% solution	Titrated with 10 ml. of 0.1 <i>N</i> glycine. As end-point was approached, colour was observed after each addition of 0.01 ml.: 0.01 0.02 0.03 0.04 0.05 0.06	—  Olive Olive-green Green Greenish blue Peacock-blue Deep blue
	200 ml. of <i>N</i> aniline in glacial acetic acid	4 ml. of 0.1% solution	Titrated with 200 ml. of <i>N</i> perchloric acid. Then added by 0.02 ml. increments	Good colour change with addition of 0.02 ml.

It will be seen from Exp. 2 (Table II) that when 10 ml. of 0.1 *N* glycine are being titrated against *N* acid there is a well-pronounced colour change with the addition of each 0.01 to 0.02 ml. of the glycine; or, in other words, the method is sensitive to one part in 1000 of the unknown. Now the sensitivity should increase in proportion to the strength of the solutions employed, and this was verified to be so in Exp. 3, in which *N* aniline was titrated against *N* perchloric acid, and it was found that the sensitiveness had increased to about 1 part in 10,000.

*Determinations of "blank corrections".*

For most of the determinations recorded an identical amount of indicator solution was taken; the magnitude of the small "blank correction" then depended virtually on the final dilution of the solution. (The indicator solution was so weak that the blank for the indicator itself was almost negligible.) The results in Table III are typical of a number of experimental determinations of the blank correction.

Table III. *Blank corrections—semi-micro-scale.*

Solution taken	Final total volume ml.	Blank correction in ml. of 0.1 N perchloric acid solution
1 ml. of 0.01 % brilliant cresyl blue in glacial acetic acid	1	0.005
1 ml. + 1 ml. of glacial acetic acid solvent	2	0.01
1 ml. + 3 ml. of glacial acetic acid solvent	4	0.02

It will be seen that under the conditions of the "semi-micro-test" the blank correction is about 1 % of the titre.

*Uses of method.*

As already indicated the method is a convenient one for estimating basic groups in isolated preparations of ampholytes or bases, and so, incidentally, for determining their combining weight. It has already been of use in this way in the characterisation of a number of substances whose structure was uncertain—*e.g.* glutathione [Harris, 1929, 2], vitamin B<sub>1</sub> (unpublished results). A further use is in determining the degree of purity of materials. For example, supposedly pure specimens of the following substances were found on test to give unexpectedly irregular titration results by this method: when their purity was tested by other means it was found that the titration results were correct and that the specimens were in fact impure (Table IV).

Table IV.

% deficiency in basic strength

No.	Specimen	As found in titration	As checked by alternative method
1	Glycylcysteine	- 17	- 18 (formaldehyde titration)
2	Glycylcysteine	- 19	- 18 (formaldehyde titration)
3	Glycyltryptophan	- 12.5	10 (N by combustion; formaldehyde titration)
4	Glycyltryptophan	- 10.5	- 10 (N by combustion; formaldehyde titration)
5	Arginine	- 7	- 8 (titration curve)

The method seems less suitable for application to crude mixtures, such for example as the unfractionated products derived from hydrolysis of proteins. In the first place the effect of various unspecific buffering substances (*e.g.* phosphate, carbonate) would have to be allowed for; secondly, added mineral acid or alkali, as well as moisture, would also have to be taken into consideration. The method has, in fact, given somewhat irregular results on several salts of amino-acids which have been tested.

*Micro-adaptation of method.*

It will be evident from the results already cited that the small departures from the theoretical values, as met with in the rather rough, or "routine" semi-micro-method described above, were not so much due to any inherent error

in the method as to such commonplace causes as slight inaccuracies in the burettes or measuring vessels, in the strengths of the solutions, or to minor irregularities in manipulation and other such subjective variations. Theoretically the method is capable of being applied on a highly micro-scale, the only limit to set upon it, practically, being the dimension of the smallest volume of titrant which can be measured by burette and of the smallest volume of solution in which a colour change can be observed. As in all micro-chemical methods, the ideal procedure is to work with the smallest possible volumes of solution rather than to use unduly weak solutions. That is to say, the brunt must be thrown on the fineness of the measuring apparatus employed rather than on dilution of the reagents. The objection to the latter alternative is that each increase in dilution increases the magnitude of the "blank" and so diminishes the sharpness of the end-point.

The micro-estimations referred to below (Table V) were taken to the nearest 0.001 ml. They were carried out by a laboratory assistant who had no previous experience of the method and who received no supervision of any kind in

Table V. *Micro-application of method.*

carrying them out. They are not intended to show the limits of the micro-method; but they do demonstrate that, even for a person with no special training, there is no difficulty in estimating quantities as small as 0.05 ml. of 0.025 *N* solution, with an error not exceeding 1-2 %. The figures given are typical of many others that were obtained at the same time.

# SUMMARY.

1. It is known that the basic groups in amino-acids, or polypeptides *etc.*, and in weak natural bases, cannot be estimated by a simple titration with HCl in water to a sharp end-point with a  $p_H$  colour indicator for the reason that the end-point is at a very acid reaction (about  $p_H$  0): a considerable "blank" is needed by the solvent (the water itself) to bring it to so acid a reaction, and there is no sudden fall in  $p_H$  to give a sharp colour change with the indicator.

2. Theoretically this difficulty is overcome if the titration is carried out in the entire absence of water. In the method described, glacial acetic acid is used as the solvent, perchloric acid in glacial acetic acid as the titrant, brilliant cresyl blue as the indicator (colour change at about  $p_H$  0 in water); whilst glycine in glacial acetic acid serves as standard base solution for back-titration. The glacial acetic acid solvent itself needs no appreciable amount of titrant (*i.e.* blank correction) to bring it to the desired end-point.

3. The estimation takes only a few moments to carry out. The dry specimen is dissolved in slight excess of the perchloric acid solution, the indicator solution is added, and standard glycine run in from a burette to give a sharp end-point. With the use of ordinary apparatus and without special precautions the error is no greater than 1 to 2 % (*e.g.* in estimations on 2 ml. of 0.1 *N* solution). On a micro-scale 0.05 ml. of 0.025 *N* solution may be estimated with no greater percentage error. The sensitiveness of the end-point is such that a definite colour change occurs with the addition of 1 part in 1000 of unknown at 0.1 *N* dilution, or with 1 in 10,000 at *N*, in titrations against *N* standard acid.

4. The method has been successfully applied to all the better known amino-acids, and to a number of polypeptides, natural bases *etc.* and to mixtures of these.

5. The principal uses of the method are (1) in determining the degree of purity of isolated specimens, (2) in characterising new or unknown substances and (3) in determining their equivalent (or molecular) weights. The material to be examined should be free from mineral acid or alkali.

# CCCXXXV. THE VITAMIN B<sub>2</sub> COMPLEX. DIFFERENTIATION OF THE ANTIBLACK- TONGUE AND THE "P.-P." FACTORS FROM LACTOFLAVIN AND VITAMIN B<sub>6</sub> (SO-CALLED "RAT PELLAGRA" FACTOR). PARTS I-VI.

BY THOMAS WILLIAM BIRCH, PAUL GYÖRGY  
AND LESLIE JULIUS HARRIS.

*From the Nutritional Laboratory, Medical Research Council and University  
of Cambridge, and the Physiological Department, University of Cambridge.*

*(Received October 31st, 1935.)*

It is now recognised that the vitamin B complex for rats contains at least three components. The position to date may be represented as follows:<sup>1</sup>

$$\text{Vitamin B} \left\{ \begin{array}{l} B_1 \\ B_2 \end{array} \right\} \left\{ \begin{array}{l} \text{Lactoflavin} \\ B_6 \\ \dots? \\ \dots? \end{array} \right.$$

The relation of the human pellagra-preventive factor (P.-P.), as well as of the canine antiblacktongue factor, to these newly differentiated components of the vitamin B<sub>2</sub> complex has remained for investigation and forms the subject of the present paper.

## *Past work.*

"Vitamin B" was first split into vitamin B<sub>1</sub> (heat labile, antineuritic or anti-beriberi factor) and vitamin B<sub>2</sub>. The latter by definition is "the more heat-stable, water-soluble dietary factor recently described and named P.-P. ('pellagra-preventive') factor by Goldberger, Wheeler, Lillie and Rogers [1926] and found necessary for maintenance of growth and health and prevention of characteristic skin lesions in rats, and considered by the latter workers to be concerned in the prevention of human pellagra" (adopted by the Accessory Food Factors Committee at a meeting on Nov. 14th, 1927). This distinction between the heat-labile and heat-stable fractions of the vitamin B complex is due mainly to the work of Goldberger.

It was assumed by Goldberger and his associates [*e.g.* Goldberger and Lillie, 1926; Goldberger *et al.*, 1928, 1, 2] that the factor which prevents the "pellagra-like dermatitis" in the rat is identical with the factor which prevents pellagra in human beings (P.-P. factor) and also with the factor which prevents "black-tongue" in dogs. Goldberger's evidence, essentially, was of a similarity in the distribution and in the heat-stability of these factors, and also of the resemblance (superficially at least) of the lesions produced by their absence.

<sup>1</sup> The "vitamin B<sub>4</sub>" of Reader is not included in this scheme. It appears that "vitamin B<sub>4</sub> deficiency" can be produced only when the animal is first deprived of vitamin B<sub>1</sub> and that it is cured whenever crystalline vitamin B<sub>1</sub> is given in sufficiently large dose. In other words "vitamin B<sub>4</sub> deficiency" has the appearance of chronic hypovitaminosis B<sub>1</sub>. As also it is described as a "heat-labile factor" it does not affect our present discussion. [For a discussion of "vitamin B<sub>4</sub>" see further Kinnersley *et al.*, 1935.]

Later work however has made the position somewhat less clear-cut. Other investigators [Chick and Roscoe, 1928; Aykroyd and Roscoe, 1929] found unexpected difficulty in producing the so-called "pellagra-like" dermatitis in the rat with any degree of regularity. They therefore used a method for estimating "vitamin B<sub>2</sub>" which depends on the resumption of growth in young rats. For this test the basal vitamin B-free diet was supplemented with "Peters's eluate" as the source of vitamin B<sub>1</sub>. Aykroyd [1930] used this method to compare the vitamin B<sub>2</sub> activities of various cereals. He reached the surprising conclusion that while all cereals were relatively poor in "vitamin B<sub>2</sub>" as so measured, maize was not in fact so deficient as were certain other cereals, namely millet and rice. Now the clinical literature indicates that pellagra is confined very largely to maize-eating communities, relatively few instances, and those in isolated cases only, having been observed where millet or rice is eaten. Aykroyd was therefore sceptical of the theory that vitamin B<sub>2</sub> deficiency—or at any rate "vitamin B<sub>2</sub>" as measured by the rat-growth test—is the cause of pellagra.

However, this objection of Aykroyd's has not been generally regarded as conclusive evidence against the theory that pellagra is a vitamin B<sub>2</sub> deficiency. As he himself indicated, other alternative explanations might be brought forward to account for the known facts. For instance, the striking difference in the incidence of pellagra on maize and rice diets might be explained by the circumstance that milled maize contains vitamin B<sub>1</sub>, whilst polished rice is completely devoid of this vitamin: hence on a rice diet—so it might be argued—the subject would develop beriberi instead of pellagra. Hence the maize eater would remain free from beriberi and so liable to fall a victim to pellagra. Secondly, the use of maize as a staple crop is generally confined to areas where there is severe economic depression: therefore individuals in a maize area are less able to supplement their diet with other foodstuffs, which may contain larger amounts of the P.-P. factor, but must rely almost exclusively on this cereal as their principal source of food. Finally it must also be remembered that no yeast is used in the baking of maize bread, and this, at first sight, might account for the difference between maize and other cereals in relation to the incidence of pellagra.

For these and other reasons it has still been generally accepted, even after Aykroyd's work, that vitamin B<sub>2</sub> deficiency is the primary cause of pellagra. It is important at this point to emphasise that carefully controlled clinical tests on human beings have shown that pellagra does clear up with dramatic rapidity and certainty when such sources of vitamin B<sub>2</sub> as liver extract or yeast are exhibited, as small supplements to a pellagra-producing diet [see *e.g.* Ruffin and Smith, 1934].

The position became more complicated when it was shown by György *et al.* [1933; 1934] that vitamin B<sub>2</sub> consists of two components, the water-soluble, yellow pigment lactoflavin and a "complementary factor". It has been later established [György, 1934; 1935, 1; Chick *et al.*, 1935; Harris, 1935] that it is not lactoflavin but the "complementary factor" (vitamin B<sub>6</sub>) which protects rats against the so-called "pellagra-like" dermatitis. Apparently the reason why the earlier workers had failed to produce symptoms of "pellagra-like" dermatitis regularly in the rat was because they used "Peters's eluate" as a source of vitamin B<sub>1</sub>; this is itself contaminated with the complementary factor.

By general agreement the complementary factor is now known in this country as vitamin B<sub>6</sub>, and the term vitamin B<sub>2</sub> is retained for the whole of the more heat-stable part of the vitamin B complex—*i.e.* excluding vitamin B<sub>1</sub>, but including lactoflavin and vitamin B<sub>6</sub> [György, 1935, 1; Chick *et al.*, 1935; Harris, 1935].

*Objects of present experiments.*

Our first object was to obtain evidence as to the identity or non-identity of vitamin B<sub>6</sub>, and of lactoflavin, with the pellagra-preventive factor (P.-P.) of Goldberger. With this aim in view we have undertaken a survey of the distribution of vitamin B<sub>6</sub> and of lactoflavin in various foodstuffs and compared the results with the known data concerning the distribution of the pellagra-preventive factor.

The second main object of the present work was to compare the behaviour of different species when fed on the various "pellagra-producing", "blacktongue-producing", or vitamin B<sub>6</sub>-deficient diets. The purpose here was to determine whether one and the same factor was concerned in the production of blacktongue, of "rat pellagra" and of various other symptoms which have been described.

We have reached the conclusion that the P.-P. factor and the antiblacktongue factor are distinct both from vitamin B<sub>6</sub> (the "rat pellagra" factor) and also from lactoflavin (see also footnote, p. 2844). Whether the P.-P. factor is identical with the antiblacktongue factor still remains for consideration. So far there seems no cogent evidence against their identity.

Very recently Elvehjem and Koehn [1934; 1935] have stated that lactoflavin does not possess "antipellagra" activity for chickens. We have investigated also this aspect of the problem; but whilst confirming some of the observations of Elvehjem and Koehn, we have been driven to the rather disturbing conclusion that the "chick pellagra" factor again is distinct from the "rat pellagra" factor, vitamin B<sub>6</sub>.

Finally the anti-anaemia "extrinsic factor" of Castle and Strauss should be alluded to. It resembles "vitamin B<sub>2</sub>" in being relatively heat-stable, and there is some similarity also in distribution [Strauss and Castle, 1932]. It has therefore sometimes been claimed that it is identical with vitamin B<sub>2</sub> (or one of its major components). Until recently it seemed that conclusive evidence was lacking either one way or the other, but we believe it may now be stated with some degree of likelihood that the extrinsic factor is also different both from lactoflavin and from vitamin B<sub>6</sub>.

## I. DIFFERENTIATION OF THE P.-P. FACTOR FROM VITAMIN B<sub>6</sub> AND LACTOFLAVIN.<sup>1</sup>

As already hinted, our conclusion that the human P.-P. factor of Goldberger differs from vitamin B<sub>6</sub> and lactoflavin is based largely on a comparison of their distribution in different foodstuffs, particularly in cereals, fish and liver extract.

It has already been reported [György, 1935, 2] that fish, although it is known to be an active source of the human P.-P. factor (*e.g.* protective dose of canned salmon = 168 g. [Goldberger and Wheeler, 1929] or flaked canned haddock = 340 g. [Wheeler, 1933]), is poor in lactoflavin. It still had to be shown how vitamin B<sub>6</sub> and lactoflavin are distributed in other natural foodstuffs, more especially in maize (since this cereal is known to be deficient in the P.-P. factor), and, for the sake of comparison, in other cereals (which appear to contain more of the P.-P. factor).

### 1. *Vitamin B<sub>6</sub> and lactoflavin content of cereals.*

The methods for the estimation of vitamin B<sub>6</sub> and lactoflavin were those previously described by György [1934; 1935, 2]. For the estimation of lactoflavin, the basal vitamin B-free diet was supplemented with crystalline (or highly purified) vitamin B<sub>1</sub> (3 I.U. daily) *plus* vitamin B<sub>6</sub> (in the form of Peters's eluate from baker's yeast: equivalent to 10 g. of fresh baker's yeast daily). For the estimation of vitamin B<sub>6</sub>, vitamin B<sub>1</sub> was similarly provided but supplemented in this instance with pure lactoflavin (10  $\gamma$  daily).

<sup>1</sup> A preliminary account of the main results in Part I has already been communicated to the Biochemical Society [Birch and György, 1935, 1].

The basal diet was as follows:

Caseinogen AB "Glaxo" ... ..	18
Rice starch ... ..	68
Butter fat ... ..	9
Salt mixture (B.D.H.) ... ..	4
Cod-liver oil ... ..	1

The values for vitamin B<sub>6</sub> are based chiefly on the curative effect against dermatitis. The values for lactoflavin were determined by means of the growth test, the skin symptoms being too irregular and frequently insufficiently obvious. The "rat day-dose", taken as provisional unit, was defined as the minimum quantity of the substance which would give rise to a gain in weight of about 10 g. per week for at least 4 weeks.

For each product graded doses were tested, generally on three rats at each level. The values given represent averages.

Table I. *Vitamin B<sub>6</sub> and lactoflavin in cereals. Summary.*

(For animal responses see Table II.)

	Lactoflavin. 1 "rat day-dose" is contained in the following weight of foodstuff g.		Vitamin B <sub>6</sub> . 1 "rat day-dose" is contained in the following weight of foodstuff g.
Wheat germ	1.0	Rice polishings	0.1
Wheat bran	1.0	Wheat germ	0.2
Pea meal	2.0	Wheat bran	0.3
Oats (ground)	3.0	White maize	0.5
Yellow maize	5.0	Yellow maize	0.75 (or less)
Rice polishings	> 1.0	Pea meal	0.75 (or less)
Whole wheat	> 5.0	Oats (ground)	1.0
Polished rice	> 5.0	Whole wheat	1.5
		Polished rice	3.0
		"Hominy grits"	3.0

As will be seen (Tables I and II), all cereals are relatively rich in vitamin B<sub>6</sub>; and maize in particular is one of the richest. The minimum curative dose of whole maize is no more than 0.5–0.75 g. per rat per day. The vitamin is not uniformly distributed throughout the grain, but the bran and the germ are the richest in it, the endosperm poorer. But even in the endosperm of white maize (in "hominy grits") there appears to be an appreciable amount of vitamin B<sub>6</sub>, the minimum curative dose being approximately 3 g. daily.

In contrast with vitamin B<sub>6</sub> the lactoflavin content of cereals is found to be very low (Table I). Indeed, in all the cereals examined the lactoflavin and not vitamin B<sub>6</sub> seems to be the limiting factor of the vitamin B<sub>6</sub> complex. Whilst the cereals are all very poor in lactoflavin, wheat contains even less lactoflavin than does maize. As with vitamin B<sub>6</sub> the germ is richer in it than is the endosperm. Rice polishings were found to be surprisingly poor in lactoflavin.

An illustration of the poverty of cereals in lactoflavin is recorded in Fig. 1.

Fig. 1. The following supplements were given daily to a diet containing adequate vitamin B<sub>1</sub> plus "Peters's eluate" (for vitamin B<sub>6</sub>). At A, 3 g. whole wheat. At B, 5 g. whole wheat. At C, 5 g. whole wheat + 10 g. lactoflavin.

Table II. *Tests on cereals etc., for lactoflavin and vitamin B<sub>6</sub>.*

(For summary see Table I.)

Material fed	Daily amount given g.	Tests for lacto- flavin (vitamins B <sub>1</sub> and B <sub>6</sub> provided). Av. weekly increase in weight	Tests for vitamin B <sub>6</sub> (vitamin B <sub>1</sub> and lactoflavin provided)

	1.0	—	3	Inconstant

Here not even 5 g. of whole wheat were able to exert a significant growth-promoting action when supplemented with vitamin B<sub>1</sub> and vitamin B<sub>6</sub>. The addition of 10γ lactoflavin then gave rise to a marked increase in weight which continued for many weeks.

*Comment.* The above results furnish a further illustration of the erroneous conclusions which may be reached if the complex nature of vitamin B<sub>2</sub> is disregarded. Since the experiments of Aykroyd and Roscoe [1929] and of Aykroyd [1930] cereals have been commonly regarded as poor in vitamin B<sub>2</sub>. As will now be seen this finding holds good only for lactoflavin, and not for the vitamin B<sub>6</sub> component of the vitamin B<sub>2</sub> complex.

## 2. Vitamin B<sub>6</sub> and lactoflavin in various foods.

Further assays on a variety of foodstuffs illustrate once again that their vitamin B<sub>6</sub> and lactoflavin contents bear no apparent relation to their reputed values as pellagra preventives (Tables III and IIIA). For example Eli Lilly

Table III. *Comparison of P.-P. value with vitamin B<sub>6</sub> and lactoflavin in various foods.*

Food	Reputed P.-P. value, after Sebrell [1934] (dose fed, g. shown in brackets)	Lactoflavin dose, 1 "rat day-dose" is contained in following weight of foodstuffs g.	Vitamin B <sub>6</sub> dose, 1 "rat day-dose" is contained in following weight of foodstuffs g.
Dried yeast	Good (15-30)	0.1-0.2	0.1-0.2

\* Expressed as weight of fresh liver.

(a) = 30 ml. per kg. of body weight.

Table IIIA. *Vitamin B<sub>6</sub> and lactoflavin values of pellagra- and blacktongue-producing diets.*

	Rat dose, g. per day	
	For vitamin B <sub>6</sub>	For lactoflavin
Human pellagra-producing diet (Ruffin and Smith)	0.5	>6.0
Canine blacktongue-producing diet (Rhoads and Miller)	0.7	6.0
"Chick pellagra" diet (Elvehjem and Koehn)	1.5	>6.0

liver extract (powder) No. 343, known to be one of the most highly potent of all antipellagra remedies (see below), contains relatively little vitamin B<sub>6</sub> whilst cereals and molasses which have little or no antipellagra activity are rich in

vitamin B<sub>6</sub>. Or again, there is no more lactoflavin in fish, which is an active source of P.-P., than in cereals, which are poor in it.

These differences are perhaps made more convincing when expressed in figures. For example, it may be seen from Table III that with maize containing 900 doses of vitamin B<sub>6</sub> there is no antipellagra action, whilst with liver extract containing less than 20 doses of vitamin B<sub>6</sub> rapid cure results (see below).

### 3. Direct clinical trials with lactoflavin.

We are allowed here to refer also to direct clinical trials carried out through the co-operation of our colleague Dr W. J. Dann at Duke University, North Carolina, which have confirmed the foregoing conclusions that the P.-P. factor is different from both lactoflavin and vitamin B<sub>6</sub>. Patients kept on the "pellagra-producing basal diet", under strictly controlled conditions (including regular exposure to light *etc.*), failed to improve when lactoflavin was administered, but they recovered rapidly and dramatically when liver extract, or other concentrated source of the P.-P. factor, was administered [Dann, *et al.* 1935]. As the basal diet itself contains maize and molasses, both rich in vitamin B<sub>6</sub>, these results indicate that neither this factor nor lactoflavin has antipellagra action for human beings.<sup>1</sup>

## II. MAIZE IN RELATION TO THE VITAMIN B<sub>2</sub> COMPLEX AND HUMAN PELLAGRA.

It is apparent from the results described in Part I that the rat antidermatitis factor, vitamin B<sub>6</sub>, is present in large amount in all the cereals examined, and particularly so in maize—*i.e.* in the "pellagra-producer" *par excellence*. Moreover the different dietaries used for the production of blacktongue in dogs, or pellagra in human beings (such as the diet of Ruffin and Smith), are also very rich in vitamin B<sub>6</sub> (curative dose for rats = 1 g. per day or less) (Tables II and III A).

It remains to be explained, therefore, how the theory came to be so generally adopted that the antidermatitis factor for the rat is identical with the P.-P. factor for human beings. We believe the explanation to be as follows. The theory had its origin in Goldberger's experiments in which dermatitis in rats was produced by means of a synthetic diet which was supplemented not with whole maize but with an extract of maize made with cold alcohol. The latter appears to be deficient in vitamin B<sub>6</sub>. It has been found [Birch and György, 1935, 2] that quantitative extraction of the vitamin from natural foodstuffs is only accomplished with difficulty. Even with extraction with hot alcohol containing HCl low yields are obtained. It may be safely concluded therefore that when cold alcohol is used very little of the vitamin B<sub>6</sub> is extracted. Unfortunately Goldberger does not appear to have attempted to use a diet containing whole maize (or milled maize), and this, as our experience indicates, is actually effective in preventing or curing rat dermatitis.

Later, when maize was examined by Aykroyd and Roscoe [1929] it was found to be a poor source of "vitamin B<sub>2</sub>"—*i.e.* of the whole "vitamin B<sub>2</sub>" complex as determined by growth tests. The explanation here, no doubt, is that there is little lactoflavin in maize: poor growth would therefore have resulted. As already indicated such experiments were merely measuring lactoflavin as the "limiting factor".

<sup>1</sup> Simpson [1935] has recently reported that a case of secondary pellagra following gastrectomy was partly improved by a "vitamin B<sub>2</sub> concentrate" from egg-white: since egg-white is deficient in vitamin B<sub>6</sub> [György, 1935, 2] this result might seem to furnish still further evidence of the differentiation of the P.-P. factor from vitamin B<sub>6</sub>.

1. *Experiments with rats fed on maize diets.*

Further experiments were also undertaken to try and ascertain whether rats need the true antipellagra factor (human P.-P. factor) or the canine antiblack-tongue factor, *i.e.* in addition to vitamin B<sub>6</sub>. In one test a group of 10 young rats was placed on the following diet, the components of which, judged by clinical experience, are deficient in the P.-P. factor:

White maize	...	...	85 %
Arachis oil	...	...	15 %
Cod-liver oil	...	...	6 drops per rat per week

This diet was supplemented with additional pure crystalline vitamin B<sub>1</sub> and lactoflavin. These additions were made to be sure that any symptoms due to possible shortage of either of these factors should not obscure the hypothetical lesions due to the lack of the P.-P. (or antiblacktongue) factor. Since exposure to light appears to play an important part in the production of the dermatitis amongst pellagrins, half of the group of rats was exposed under a quartz mercury-vapour lamp for half an hour each day.<sup>1</sup>

The growth curves of this group of animals are shown in Fig. 2. It is seen that both the irradiated and the non-irradiated animals had subnormal growth rates. At the point on the curve marked ↓ (102 days from the beginning of the experiment) an addition of 10 % of caseinogen was made to the diet and the maize

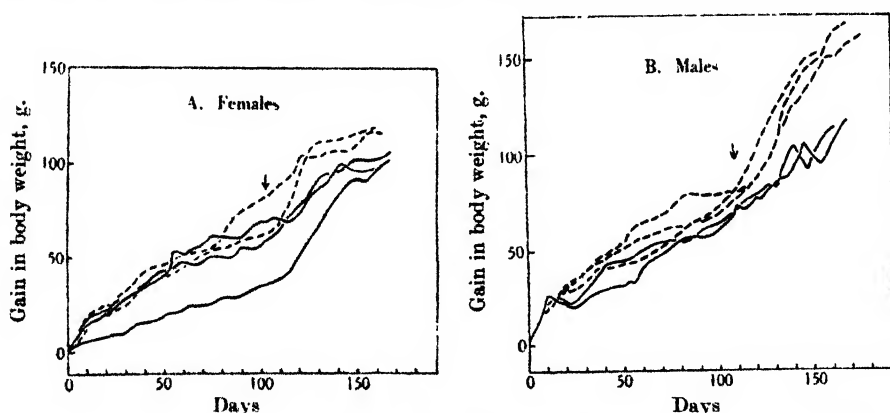

Fig. 2. Growth curves of rats fed on diet deficient in P.-P. factor. A, females; B, males. — non-irradiated animals. - - - irradiated animals. Caseinogen given at ↓.

reduced to 75 %. At this time some of the animals had begun to show bald patches and loss of fur together with a slight scurfy condition of the skin. With this addition of caseinogen however the growth rate increased and the fur became almost normal again. It is thought therefore that these symptoms were probably due to the lack of an essential amino-acid, perhaps cystine or tryptophan. Subsequently the irradiated animals developed small brown scales on their

<sup>1</sup> Aykroyd [1930] had previously attempted without success to produce the pellagra-like dermatitis in rats by feeding a maize diet and submitting the animals to ultraviolet irradiation. His experiment differed from ours in that he fed Peters's eluate as a source of vitamin B<sub>1</sub>; this might possibly contain the P.-P. factor. Also the period of irradiation was limited to 3 min. per day. The possibility therefore remained that with supplements of pure vitamin B<sub>1</sub> plus lactoflavin, and with the amount of irradiation increased some 10 times, symptoms due to the lack of the true P.-P. factor might appear.

backs, and a whitish opacity was seen on the eyeballs, due apparently to the excessive irradiation with ultraviolet light. Nevertheless, characteristic skin lesions analogous to pellagra were not seen and diarrhoea, a characteristic symptom in pellagra, was absent.<sup>1</sup>

It appears therefore that rats do not need the P.-P. (or antibleblacktongue) factor (or their needs are remarkably small), or, as with vitamin C, are able to synthesise it for themselves. Experiments are at present in progress on this last point.

## 2. Absence of pellagra from rats fed on blacktongue or human pellagra-producing diets.

A further group of rats was fed on the diet given below (Goldberger diet), which is more closely based on that used by Goldberger *et al.* [1928, 1, 2] for the production of blacktongue in dogs, and which we ourselves have confirmed (see Part III) to be satisfactory for this purpose. All the rats thrive on this diet (see Fig. 3), and remained free from skin lesions, although eventually their

Fig. 3. Growth curves of rats fed on Goldberger blacktongue diet plus vitamin B<sub>1</sub> and lactoflavin.

growth rates became subnormal. Further tests were also made with diets similar to those used for experimental work on pellagra in human beings (see below) and with the same result.

## Composition of pellagra-producing diets (after Ruffin and Smith [1934]).

### Goldberger diet.

	g.		g.
Corn meal	229	Cane sugar	58
Grits	29	Sweet potatoes	92
Corn starch	35	Turnip greens	21
Wheat flour	137	Cabbage	9
Rice	23	Collards	13
Cane syrup	34	Pork fat	107

### Ruffin and Smith diet.

	g.		ml.
Corn meal	92	Cod-liver oil	90
Cane sugar	105	Tomato juice	45
Flour	111	Iron ammonium citrate	6
Lard	81	Calcium gluconate	6
Rice	25	Cheese	60
Field peas	90		
Hominy grits	51		
Fat salt pork	60		

<sup>1</sup> It appears that the irradiation had a beneficial effect on the animals, for in all cases the irradiated ones grew better than the non-irradiated. After 166 days the irradiation was stopped and the rats were mated. Three out of the five does produced litters, the two not having litters being both from the non-irradiated group. Such a result suggests that the diet is not grossly deficient in any factor needed by the rat, although the young rats died shortly after birth.

### III. DIFFERENTIATION OF THE "ANTIBLACKTONGUE" FACTOR FROM VITAMIN B<sub>6</sub> AND LACTOFLAVIN.

The purpose of the experiments to be described in this section was to produce symptoms of blacktongue in dogs and test the curative and preventive actions of the known components of the vitamin B<sub>2</sub> complex.

#### 1. *Experiments with Goldberger's blacktongue-producing diets.*

*Diet.* In the first experiment 3 young bitches of about 6–7 kg. in weight were placed on a basal diet slightly modified from that of Goldberger *et al.* [1928, 1] and Rhoads and Miller [1935, 1].

White maize meal	...	...	...	...	...	...	600
Dried pea meal	...	...	...	...	...	...	75
"Glaxo" extracted caseinogen ("free from vitamin B <sub>2</sub> ")	...	...	...	...	...	...	90
Cod-liver oil	...	...	...	...	...	...	28
Cottonseed oil	...	...	...	...	...	...	45
CaCO <sub>3</sub>	...	...	...	...	...	...	45
NaCl	...	...	...	...	...	...	15

As will be seen from the results given in Part I this diet is rich in vitamin B<sub>6</sub> but contains only small quantities of lactoflavin.

To prepare the diet, the maize meal, the pea meal and the caseinogen were cooked in a double saucepan for 2 hours and the other ingredients added subsequently. The diet was offered *ad lib.* About 100–200 g. were consumed by each dog per day. All dogs received a daily injection subcutaneously of 80 I.U. of vitamin B<sub>1</sub>. This was given in the form of a highly active concentrate, free from lactoflavin and vitamin B<sub>6</sub>. We are indebted to Messrs I. G. Farbenindustrie of Germany for their generosity in supplying this preparation.

*Experimental observations.* One dog, kept as a positive control, was given autoclaved yeast, 10% by weight of the diet. In contrast with the other animals, this one grew well, remained in excellent health and had none of the characteristic symptoms. During the latter part of the experiment an additional supplement of lactoflavin was provided with no apparent influence on the progress of the animal, showing that the amount of lactoflavin in the added autoclaved yeast was already adequate.

The two dogs on the unsupplemented blacktongue-producing diet lost weight rapidly, and became emaciated and increasingly weak (see Fig. 4). After 76 days, incipient lesions were just distinguishable on their tongues, in the form of transverse ridges on the upper surface. Lactoflavin was then administered, 30γ per kg. body weight per day, intraperitoneally. It failed to protect the animals, for the loss in weight continued, diarrhoea developed, and the condition of the tongue quickly deteriorated. In another fortnight the tongues had become markedly pale, the ridges across the surface were more pronounced and there was some atrophy at the edges. Excessive salivation was prominent in one dog.<sup>1</sup>

*Cures with liver extract and fish.* After the dogs had been 102 days on the experimental diet, one was treated with a supplement of 4 g. per day of Eli Lilly powdered liver extract No. 343 (= 100 g. fresh liver), and the other with 35 g. per day of fresh herring. In both dogs, the improvement was dramatic. They

<sup>1</sup> Although the lactoflavin clearly had no specific action against "blacktongue" it seems likely that it is a necessary component of the diet of the dog, as of the rat. Following its administration the dogs seemed more lively and alert and the loss in weight less steep.

immediately started gaining weight again, and already after 5 or 6 days the tongue showed some improvement; the general behaviour and appearance of the dogs changed from one of dejected apathy to normal liveliness.

Fig. 4. Experiments with dogs on Goldberger blacktongue diet. No. 1, positive control, received autoclaved yeast, 10% of diet daily. Starting from arrows marked " $B_1$ ", 80 i.v. of vitamin  $B_1$  were given daily; from "Lactoflavin" 30% of lactoflavin per kg. body weight were injected daily; at "Liver extract" (dog No. 2) 4 g. of Eli Lilly liver powder 343 (= 100 g. fresh liver) daily; and at "Herring" (dog No. 3) 35 g. fresh herring daily.

*Second experiment.* On the 114th day the curative supplements of liver extract and herring were discontinued. At once the animals began to lose weight again. They died on the 140th and 134th day respectively from the beginning of the tests.

*Blood counts.* A few days from the end of the experiment determinations of haemoglobin and red blood cells were carried out by Dr M. A. Abbasy. His fuller results will form the subject of a later communication; but it may be noted that pronounced anaemia was present in the animals suffering from blacktongue.

Table IV.

	Haemoglobin value %	Red blood cells per $\mu$ l.
Blacktongue	40	3,320,000
Blacktongue	35	2,500,000
Positive control	88	5,200,000

**Post mortem findings.** The two dogs which died under the influence of the deficient diet were examined by Dr J. R. M. Innes of the Institute of Animal Pathology, who stated that their condition conformed with that described for "blacktongue" by Goldberger, and by Rhoads and Miller and others.

**Conclusions.** It is apparent that the dogs lost weight and developed "blacktongue", with symptoms of diarrhoea, anaemia *etc.*, on a diet containing relatively large amounts of vitamin B<sub>6</sub>. The addition of large quantities of lactoflavin was also unable to protect against the disease, whereas small amounts of autoclaved yeast, fresh fish or liver extract, containing relatively little additional vitamin B<sub>6</sub> or lactoflavin, prevented or cured the symptoms. (The calculated amounts of vitamin B<sub>6</sub> or lactoflavin in this basal diet and in the various supplements are shown in Table V.) It may be concluded that the "blacktongue" factor present in the autoclaved yeast, in the liver extract and in the herring is distinct from lactoflavin or vitamin B<sub>6</sub>.

Table V.

	No. of rat units		Result (protection against blacktongue)
	Vitamin B <sub>6</sub>	Lactoflavin	
Basal diet alone (approximately 150 g. per day)	230	22	No protection
" + lactoflavin	230	50	"
" + lactoflavin + 35 g. herring per day	300	50	Protection
" + lactoflavin + 4 g. liver extract per day	240	100	"
" + lactoflavin + 10% autoclaved yeast	275	95	"

## 2. Experiments on synthetic diets.

So far as we can tell from a study of the literature, past workers who have used dogs for the study of blacktongue have usually restricted their attention to the use of "natural" diets, and have apparently not succeeded in maintaining dogs satisfactorily on "synthetic" diets. However, it seemed desirable, for scientific accuracy, to attempt to work with the "synthetic" type of diet, in order that the various dietary components might be more accurately controlled and varied. Our experiments indicate that this is in fact possible. Control dogs fed on the "synthetic" diet *plus* 7% of yeast thrived normally (Figs. 5 and 6). The composition of the basal diet used throughout these experiments was as follows:

Cane sugar	...	...	...	67
Extracted caseinogen	...	...	...	20
Salt mixture	...	...	...	3
Arachis oil	...	...	...	10
Cod-liver oil	...	...	...	20 ml. per day

From the earlier results it might be anticipated that this basal diet, even when supplemented with vitamin B<sub>1</sub> *plus* lactoflavin, is still deficient in not one but in two factors—namely the "rat pellagra factor" (vitamin B<sub>6</sub>) and the anti-blacktongue factor. Former workers have wrongly assumed that these two are identical. Our supposition seems confirmed by the observations recorded in Fig. 7. Here a dog receiving vitamin B<sub>1</sub> and lactoflavin was not cured when vitamin B<sub>6</sub> was added in the form of maize (50 g. per day of cooked white maize meal), but was cured with the further addition of the antiblacktongue factor, given in the form of liver extract 343. Further tests on other dogs (Figs. 8, 9 and 10) uphold this view, namely that the dog is unable to thrive when given either of these supplements separately, but does so when the two are combined. That this result is quantitatively significant—and is not due to the second supplement augmenting the amount of vitamin B<sub>6</sub> in the first supplement—is

seen from the contrasting vitamin values given in Table VI. The individual effects of deficiency of vitamin B<sub>6</sub>, lactoflavin and the antiblacktongue factor in the dog are still under investigation.

Table VI.

	Vitamin B <sub>6</sub>	Antiblacktongue factor
White maize meal, 50 g. per day	100 rat units	0
Liver extract, No. 343, 4 g. per day (=100 g. fresh liver)	< 10 rat units	+++

*Comments.* Observations by earlier workers have tended to suggest that the presence of maize is a necessary condition for the production of symptoms of blacktongue in dogs. (Many have supposed that maize contains a pellagra-producing, or blacktongue-producing, toxin [cf. Chick, 1933].) Recently Cowgill *et al.* [1934] have reported that on artificial vitamin B<sub>2</sub>-deficient diets containing no maize the symptoms which develop are different from those of blacktongue, being marked by stomatitis and glossitis: Zimmerman and Burack [1934] indeed suggest that "blacktongue", as ordinarily observed, may be a multiple deficiency. The experimental results recorded in this section point to the following as a possible explanation of such observations: namely, that the addition of maize to the diet helps in the production of regular symptoms of blacktongue, not so much because of a toxin present in it, as because in its absence the dog may sometimes develop earlier vitamin B<sub>6</sub> deficiency instead of blacktongue.<sup>1</sup>

#### IV. OBSERVATIONS WITH CHICKENS AND OTHER SPECIES.

The observations made in Parts I-III indicate that there are considerable differences between species in their need for the components of the vitamin B<sub>2</sub> complex, the rat appearing to differ markedly from the dog or the human being. It was thought advisable to pursue this aspect of the problem by observations on a variety of other species. We wish here to record our observations on chickens, mice, rabbits and guinea-pigs.

##### 1. "*Chick pellagra*" of Elvehjem and Koehn.

Elvehjem and Koehn [1934; 1935] recorded that chicks fed on the following diet:

Maize meal	...	...	...	580
Middlings	...	...	...	250
Extracted caseinogen	...	...	...	120
Common salt	...	...	...	10
Calcium carbonate	...	...	...	20
Cod-liver oil	...	...	...	2% daily

(the maize meal, middlings and extracted caseinogen are heated in shallow trays at 100° for 144 hours)

developed skin lesions (considered by them to be the analogue of human pellagra). The lesions were not cured by lactoflavin. We have confirmed the

<sup>1</sup> A recently published preliminary note by Rhoads and Miller [1935, 2] states that rats do not develop vitamin B<sub>2</sub> deficiency when fed on Goldberger diet. These authors postulate therefore that blacktongue is not due to a deficiency of "vitamin B<sub>2</sub>". This experimental observation with rats is independently confirmed in Part I, but our own results with dogs lead to a rather different summing up of the position: that is, that the antiblacktongue factor is found to be distinct from two known constituents of the vitamin B<sub>2</sub> complex, namely vitamin B<sub>6</sub> and lactoflavin, but is to be regarded as an additional constituent of the vitamin B<sub>2</sub> complex, possibly identical with the human P.-P. factor. So far we have been able to find no cogent evidence to distinguish the canine blacktongue factor from the human P.-P. factor.

findings of Elvehjem and Koehn that chicks fail to thrive on this diet and may develop skin lesions, especially around the beak (which however in our experiments were not very well marked). Loss in weight and skin symptoms are prevented when yeast is added to the diet, or if the diet is fed in an unheated condition instead of after the heating process (see Fig. 11). In accordance with the

Fig. 11. Chicks on various modifications of Elvehjem-Koehn diet. In group I (heated E.K. diet), 10 I.U. of vitamin B<sub>1</sub> and 30  $\gamma$  of lactoflavin were injected twice weekly. "D" indicates incidence of dermatitis. Group II. Heated E.K. diet + 7% dried yeast. Group III. Unheated E.K. diet.

findings of Elvehjem and Koehn, lactoflavin had no effect on the symptoms. On the other hand we believe that the "chick pellagra" factor of Elvehjem and Koehn is different from vitamin B<sub>6</sub>, for we have found that rats fed on this diet remain free from any symptoms of vitamin B<sub>6</sub> deficiency, and in fact the diet cures rats suffering from vitamin B<sub>6</sub> deficiency in doses of 1.5 g. per day (see Table II).<sup>1</sup>

The nature of the deficiency (or deficiencies) in the diet of Elvehjem and Koehn seems for the moment uncertain. We have noted that rats fed on it show a subnormal growth rate and a premature flattening of the growth curve (Fig. 12) after a time, although, as remarked above, they remain free from the skin lesions of vitamin B<sub>6</sub> deficiency. This might appear to indicate a deficiency in the Elvehjem-Koehn diet of some additional factor which is needed by the rat and hence is presumably different from the P.-P. or antiblacktongue factor (which the rat appears able to dispense with or at any rate to require in only very minute amounts (Parts I-III)).

A further observation we have made is that chicks fed on Elvehjem-Koehn diet supplemented with yeast show a condition suggestive of anaemia, as judged by the strikingly pale condition of their combs. The anaemia-preventing factor concerned, therefore, as it is not contained in yeast, should not perhaps be regarded as a component of the vitamin B<sub>2</sub> complex. When unheated Elvehjem-Koehn diet was fed the anaemia was found to be entirely prevented.

<sup>1</sup> Since this was prepared for press Lepkovsky and Jukes [1935] have also published the conclusion (reached by a quite different line of evidence from our own) that the Elvehjem-Koehn chick factor is distinct from the rat "vitamin G".

Fig. 12. Rats fed on Elvehjem-KoeHN "chicken pellagra" diet with various modifications.

Fig. 13. Mice fed on various vitamin B-deficient diets. (In groups II and IV vitamin B<sub>1</sub> was given as 5 I.U. injected twice weekly and lactoflavin as 15  $\gamma$  injected twice weekly.) Group I. Goldberger blacktongue diet plus 7% fresh dried yeast. Group II. Goldberger blacktongue diet plus vitamin B<sub>1</sub> and lactoflavin. Group III. Synthetic vitamin B-deficient diet plus 7% fresh dried yeast. Group IV. Synthetic vitamin B-deficient diet + vitamin B<sub>1</sub> + lactoflavin.

## 2. Mice.

Preliminary observations with mice show that they fail to grow and develop loss of hair with slight skin lesions when kept on a synthetic diet, supplemented with vitamin B<sub>1</sub> plus lactoflavin (5 I.U. and 15  $\gamma$  respectively, injected twice weekly). Addition of yeast improves their condition (Fig. 13). It is possible therefore that mice may prove a useful and convenient experimental species for the investigation of the vitamin B<sub>2</sub> complex and further investigations are in progress. So far all mice fed on Goldberger's blacktongue diet, on which rats are able to thrive, have lost weight and succumbed.

## 3. Guinea-pigs and rabbits.

Attempts to produce "vitamin B<sub>2</sub>" deficiency in rabbits or guinea-pigs, by the feeding of modified Goldberger-blacktongue diets, or synthetic diets, were unsuccessful, as the animals failed to eat sufficient quantities of food.

V. VITAMIN B<sub>6</sub> AS THE RAT ANTI-ACRODYNIA FACTOR.

Previous workers have referred to the dermatitis seen in rats on vitamin B<sub>2</sub>-deficient diets as being "pellagra-like". But, as has been pointed out above, this specific lesion is due to deficiency of vitamin B<sub>6</sub>—a factor which is certainly different from the antipellagra (P.-P.) factor of Goldberger. It would therefore be misleading to refer to the results of vitamin B<sub>6</sub> deficiency, certainly in their dermatological aspects, as "pellagra-like". Furthermore the "dermatitis" of vitamin B<sub>6</sub> deficiency differs in its clinical picture from pellagra as seen in human beings. For instance it seems to have no relation to light sensitisation; there is no association with diarrhoea, and there are other marked differences. On the other hand, it has certain very characteristic features of its own, involving chiefly the most peripheral parts of the body, such as the paws, the nose and the ears. The condition resembles a peculiar disease of infancy, known as "pink disease", Swift's disease, or acrodynia. This latter term is appropriate as giving an accurate description of an outstanding feature of the disease, namely the localisation of the most affected parts.

This is not the first time that a possible connection has been discussed between pink disease and skin alterations produced experimentally in rats. Findlay and Stern [1929] emphasised the similarity between acrodynia in man and certain pathological changes occurring in young rats fed on a diet rich in egg-white. On the other hand, Parsons [1931] and others have stressed the "pellagra-like" appearance of the condition produced by the "egg-white injury" [Boas, 1927].

Our own observations lead to the conclusion that the "egg-white injury" is distinct from vitamin B<sub>6</sub> deficiency. The most characteristic feature of vitamin B<sub>6</sub> deficiency is that the earliest and most distinctive lesions appear on the peripheral parts of the body (ears and paws), whereas in the "egg-white injury" the extremities are not necessarily affected. The factor, the deficiency of which is responsible for the "egg-white injury", was termed "factor X" by Boas, and appears to correspond with "vitamin H" of György. The latter has been differentiated from vitamin B<sub>6</sub> and lactoflavin and has widely dissimilar chemical properties. For instance, vitamin B<sub>6</sub> is basic, whilst vitamin H is an acid ampholyte.

The characteristic acrodynia type of abnormalities in rats has been seen only in vitamin B<sub>6</sub> deficiency. We propose therefore to name this specific dermatitis *rat acrodynia*—without prejudice as to its identity or otherwise with human acrodynia.

## VI. THE EXTRINSIC FACTOR FOR PERNICIOUS ANAEMIA.

Before it was recognised that vitamin B<sub>12</sub> was complex in nature Strauss and Castle had reported [1932] that the extrinsic factor for pernicious anaemia bore a resemblance to vitamin B<sub>12</sub> both in its distribution in nature and also in its heat-stability. Strauss and Castle believed that the two substances might be identical. This latter conclusion was disputed by Wills and Naish [1933], but more recently Miller and Rhoads [1934] have given cogent reasons for questioning the validity of Wills's proof. But now that two separate constituents of vitamin B<sub>12</sub> have been characterised, as lactoflavin and vitamin B<sub>12</sub>, the whole question demands reconsideration.

A clue to the probable non-identity of the extrinsic factor with vitamin B<sub>12</sub> or lactoflavin may be found in the work of Miller and Rhoads [1934]. These workers have found that two materials in particular serve as highly potent sources of extrinsic factor, namely egg-white and an acetone extract of rice polishings. Now egg-white is known to be deficient in vitamin B<sub>12</sub> [György, 1935, 2], and rice

contains very meagre amounts of lactoflavin, and acetone extracts of it, no doubt, still less. Unless therefore it can be shown that other sources of the extrinsic factor are in fact active in much smaller doses than hitherto considered likely, this finding of Rhoads and Miller seems to rule out the possibility of either vitamin B<sub>6</sub> or lactoflavin being the extrinsic factor.

The liver substance curative of pernicious anaemia (which is held to be the result of the interaction of this extrinsic factor with the intrinsic factor of the gastric juice) clearly cannot be identical with any constituent of vitamin B<sub>6</sub>, since yeast, without previous digestion, is inactive [Cohn *et al.*, 1928; Strauss and Castle, 1932].

#### DISCUSSION.

The principal conclusions to be drawn from the experimental work described in Parts I to VI may now be given as follows. The human P.-P. factor is different both from the rat vitamin B<sub>6</sub> and from lactoflavin. The canine antiblacktongue factor is also different from vitamin B<sub>6</sub> and lactoflavin: it may be identical with the P.-P. factor. Human pellagra is a distinct condition from rat pellagra, and much past evidence based on their supposed identity must accordingly be abandoned. Perhaps the most striking evidence for the differentiation of vitamin B<sub>6</sub> from P.-P. and the antiblacktongue factor is the finding that maize is so rich in vitamin B<sub>6</sub>.

The question which will now be raised is, What is the nutritional significance of vitamin B<sub>6</sub> for human beings and for dogs? Further work will have to be undertaken to examine this problem.

An objection which may possibly be advanced to our differentiation of the P.-P. and antiblacktongue factors from vitamin B<sub>6</sub> is to suppose that the difference is merely one of degree—*i.e.* that the factors are identical but that dogs and human beings merely need more than do rats. This criticism is immediately answered by a study of Tables IIIA and V which show that blacktongue in dogs and pellagra in human beings are produced by diets extremely rich in vitamin B<sub>6</sub> and are cured when supplements are given containing no more than a slight trace of it. The same argument applies also to the differentiation of lactoflavin from the human pellagra and canine blacktongue factor.

It might be suggested that perhaps the vitamin B<sub>6</sub> in maize is readily absorbed by a rat, but, for some reason, inaccessible to a human being or to a dog. There is however no evidence to favour such a supposition; on the contrary it may be pointed out that fish, from which vitamin B<sub>6</sub> can be recovered less readily by treatment with solvents, is a potent source of P.-P. (or antiblacktongue) factor, whilst maize, from which vitamin B<sub>6</sub> is more readily dissolved, is deficient in P.-P. Moreover, treacle, which is rich in vitamin B<sub>6</sub> and contains it in an immediately soluble form, has no P.-P. activity (molasses being indeed a principal constituent of the human pellagra-producing diet—"the three M's"—maize-meal, meat (= salt pork) and molasses).

Finally allusion should be made to the commonly held view that pellagra is caused by a toxin assumed to be present in maize. It should be pointed out that, even if such a toxin be concerned in the production of pellagra, it is none the less apparent from the controlled clinical observations of Ruffin and Smith [1934] and others, that the lesions are readily cured by small amounts of a special substance—which therefore deserves the designation of the antipellagra vitamin or "P.-P. factor"—a substance which is present in liver extract and certain other sources, and which as we have shown is distinct both from the so-called "rat pellagra" factor (vitamin B<sub>6</sub>) and from lactoflavin—the two hitherto recognised constituents of the vitamin B<sub>6</sub> complex.

## SUMMARY.

I. The human pellagra-preventing ("P.-P.") factor is different both from vitamin B<sub>6</sub> (hitherto called the "rat pellagra" factor) and from lactoflavin, two known components of the vitamin B<sub>2</sub> complex.

There are marked differences in distribution. Thus, maize and molasses, which are known to be deficient in P.-P. are rich sources of vitamin B<sub>6</sub>, whilst liver powder "343" is rich in P.-P. but deficient in vitamin B<sub>6</sub>. Fish which is moderately rich in P.-P. is relatively deficient in lactoflavin. Further data are given of the distribution of vitamin B<sub>6</sub> and lactoflavin in various cereals and other products and are contrasted with the known distribution of the P.-P. factor.

Furthermore lactoflavin fed direct to human pellagrins [Dann *et al.*, 1935] in controlled tests under standardised conditions failed to cure, whereas known sources of P.-P., such as liver extract *etc.*, gave dramatic cures. The basal pellagra-producing diet used in these trials was itself rich in vitamin B<sub>6</sub>, which again illustrates the difference between P.-P. and vitamin B<sub>6</sub>.

The P.-P. factor should therefore be regarded as a third component of the vitamin B<sub>2</sub> complex.

II. Rats were fed on known pellagra-producing diets identical with those used in clinical experiments, or based on diets actually consumed by pellagrins, and on blacktongue-producing diets. Such rats, even although exposed to intensive irradiation remained free from symptoms of pellagra. On the other hand, rats suffering from vitamin B<sub>6</sub> deficiency (misnamed "rat pellagra") were cured when these pellagra-producing diets were fed.

"Rat pellagra" therefore is not the analogue of human pellagra, but is a separate condition. The mistaken identification of "rat pellagra" with human pellagra had its origin in experiments by Goldberger, in which alcoholic extracts of maize (containing no vitamin B<sub>6</sub>) were unfortunately used in the diet, in lieu of maize itself which is a potent source of vitamin B<sub>6</sub>.

Rats do not need the human P.-P. (or canine blacktongue) factor in any significant amount, or are able to synthesise it.

III. Dogs lost weight and developed "blacktongue" with symptoms including diarrhoea and anaemia when fed on a Goldberger maize diet containing large amounts of vitamin B<sub>6</sub>. The addition of lactoflavin had no curative action. Symptoms were prevented or cured by the addition of supplements of autoclaved yeast, fresh fish (containing negligible lactoflavin), or Eli Lilly liver powder, 343 (containing negligible vitamin B<sub>6</sub>).

It is therefore concluded that the antiblacktongue factor is different from lactoflavin or vitamin B<sub>6</sub>. It may be identical with the human P.-P. factor, but evidence is so far not conclusive.

Dogs kept on "synthetic" diets containing vitamin B<sub>1</sub> and lactoflavin, appear to need supplements of two further factors, one contained in maize (presumably vitamin B<sub>6</sub>) and one in liver extract (P.-P. or antiblacktongue factor). It is supposed that the addition of maize to the diet helps in the production of regular symptoms of blacktongue, not so much because of a toxin present in it, but because in its absence the dog may sometimes develop earlier vitamin B<sub>6</sub> deficiency instead of blacktongue.

IV. So-called "chicken pellagra" of Elvehjem and Koehn appears to be distinct from vitamin B<sub>6</sub> deficiency, and its relation to human pellagra and blacktongue is undecided. An anti-anaemia factor is destroyed in the method of preparation of the Elvehjem-Koehn diet.

Preliminary observations on vitamin B<sub>2</sub>-deficient mice are recorded.

Guinea-pigs and rabbits appear unsuitable for work on vitamin B<sub>2</sub>.

V. Since vitamin B<sub>2</sub> deficiency is most characteristically a disease of the extremities and the lesions are not truly "pellagra-like", it would be more appropriate to call vitamin B<sub>2</sub> the "rat acrodynia factor".

VI. The extrinsic factor for pernicious anaemia also appears to be different from lactoflavin or vitamin B<sub>6</sub>.
